Keywords: Dynamic network, modeling, language, graphical specification.

Abstract: We present a language, MEADOW, for specifying dynamic networks from a structural viewpoint. We demonstrate MEADOW in three examples addressing dynamic reconfiguration in the setting of object-oriented networks, ad hoc networks and mobile code networks. MEADOW is more expressive than any language of this kind (e.g. SDL-2000 agent diagrams, composite structures in UML 2.0) that we are aware of, but maintains, in our opinion, the simplicity and elegance of these languages.

1 INTRODUCTION

Progress in the history of software engineering can be characterized by the introduction of levels of abstraction to languages and methods with which to develop computerized systems. Indeed, raising the level of abstraction has been said to improve the cost of production, longevity, and quality of software systems (Frankel, 2003).

Graphical languages enable specification of computerized systems at a level of abstraction far higher than the level of zeros and ones, and many state-of-the-art languages such composite structures in UML 2.0, are useful for describing the static structure of networks without capturing detailed information about implementation or execution. Today however, networks which exhibit dynamic reconfiguration such as object-oriented networks (Korson and McGregor, 1990), ad hoc networks (Bae et al., 2000; Basagni, 1999; Lee et al., 1999) and mobile code networks (Fuggetta et al., 1998) are of great practical importance, and many graphical specification languages lack concepts with which to express dynamic reconfiguration at a high level of abstraction.

Having recognized the importance of abstraction and the wide use of dynamic networks, it is our belief that raising the level of abstraction on which dynamic reconfiguration may be specified is beneficial. In this paper, we aim to address this by proposing concepts with which to describe dynamic reconfiguration in structural diagrams through the introduction of the graphical language, MEADOW (ModElling lAn-guage for DataflOW). We distinguish between diagrams for specifying snapshots of the network structure at one point in time, and diagrams for specifying the potential structure that networks may exhibit over a period of time. A diagram of potential structure contains information about dynamic reconfiguration in the sense that it constrains the potential structure that a network may exhibit during its lifetime. Snapshot diagrams may be used to model the structure that a network may exhibit at the time of creation and at later points in time. Snapshot diagrams can be related in time to model dynamic reconfiguration. In addition, MEADOW distinguishes clearly between static and dynamic constructs in order to capture both static and dynamic aspects of networks.

The contributions of this paper are: (1) A conceptual model for dynamic networks. (2) Concepts for constraining the potential structure that a network may exhibit over a period of time. (3) Concepts for relating snapshot diagrams in time. (4) The application of these concepts in examples of three kinds of dynamic networks: object-oriented networks, ad hoc networks, and mobile code networks.

The rest of the paper is structured as follows. In section 2, we define the basic network related terms used in this paper. Section 3 aims to provide sufficient background on MEADOW to allow the examples to be understood. In section 4, 5 and 6 we employ MEADOW to specify the structure of three kinds of dynamic networks. Section 7 describes related work.
and section 8 concludes this paper.

2 NETWORK CONCEPTS

In order to define a small set of terms with which to describe networks, we abstract from the distinction of physical and logical layers. We say that a network is a set of components and a set of channels over which the components communicate. Networks that consist of computers that are connected by fixed wires, or networks that consist of application processes connected by TCP/IP, are thus conceptualized in the same way.

In the following we define basic network concepts and use these concepts to define three kinds of dynamic networks: object-oriented networks, ad hoc networks and mobile code networks.

2.1 Basic network terms

The UML class diagram in figure 1 describes the relationships between the basic network terms that are used in this paper. The definition of these terms is based on well-established constructs from existing languages and methods (Broy and Stølen, 2001; Grosu and Stølen, 2001; ITU-T, 2000; OMG, 2003).

Network A set of components, a set of channels over which the components communicate, and a set of sub-networks. We distinguish between a network type and a network instance. A network type defines a set of common features shared by all of its instances, whereas a network instance has its own identity and its own set of properties that conforms to the features defined by its type.

Component An entity that communicates with its environment through a set of referenced ports. A component may be sent from one component to another via channels. A component has a behavior which defines (1) how messages that are received by its referenced ports are handled, and (2) how messages are output on its referenced ports. We distinguish between a component type and a component instance. A component type defines a set of common features shared by all of its instances.

Each component instance is of a specific type, and has its own identity and its own set of properties that conforms to the features defined by its type. A component can be elementary or composite.

Elementary Component A component that can not contain sub-components or channels.

Composite Component A component that may contain (reference) sub-components and channels over which the sub-components may communicate. A composite component may communicate with its sub-components.

Port A port provides an interface between a component and its environment. A port is either an input-port or an output-port. The former receives messages from a channel, whereas the latter transmits messages along a channel. A reference to a port may be sent from one component to another via a channel.

Channel A channel represents the forwarding of messages from an output-port to an input-port, hence a channel is directed. A channel is shared if any of the ports it connects are referenced by more than one component. A channel may or may not allow message overtaking, message disappearance, and message duplication.

2.2 Static, Dynamic and Mobile Networks

Based on the terms introduced in the previous subsection, we define what we mean by static and dynamic networks. The following terms are defined with respect to a model of a network. Consequently, whether we say that a network is dynamic or not depends on how the network is specified, and not necessarily on the network itself (das Ding an sich).

The terms defined below are understood in various ways depending on context and research field. Our definitions are not meant to cover or encompass all of these understandings, but rather to make precise what we mean by these terms in MEADOW and in this paper.

Static network A network is static if the sets of references to ports and sub-components of all its components remain constant throughout any computation. Hence, in a static network, components and channels are neither created nor killed during computation.

Dynamic network A network is dynamic if (1) the sets of references to ports and sub-components of one or more of its components do not remain constant throughout a computation or (2) the set of components that are part of the network does not remain constant throughout a computation.
Object-oriented network A dynamic network in which (1) each component references a single input-port and may reference many output-ports, and (2) references to output-ports may be sent along the channels. In other words, a component represents an object, and the single input-port referenced by the component represents a unique object identifier. The output-ports referenced by a component represent object identifiers of other components (pointers) that the component is aware of. References to output-ports that may be sent along the channels represent object identifiers (pointers) that may be passed on from one object to another.

Ad hoc network A dynamic network in which (1) each of the components in its set may be removed from that set during computation, i.e. every component may enter or leave the network during the lifetime of the network and (2) all the components may change their communication partners during the lifetime of the network. An object-oriented network is a special case of an ad hoc network.

Mobile code network A network which enables a component (representing the mobile code) to be sent on a channel from one (composite) component to another (composite) component.

3 MEADOW BASICS

In MEADOW, there is no graphical notation for networks, components and channels. Instead they are modeled by so-called regions, parts and connectors\textsuperscript{1}, respectively.

Assume that I is a set of identifiers, \( n \) is a natural number, and that \( T \) and \( i \) are identifiers. Unless otherwise specified, the following applies throughout the rest of the paper:

- \( \cdot T \) denotes either (1) a component type named \( T \) or (2) a network type named \( T \).
- \( T[n] \) denotes \( n \) unnamed instances of \( \cdot T \).
- \( i:T \) denotes an instance named \( i \) of \( \cdot T \).
- \( i:T \) denotes \( \theta:T \) for each \( \theta \in I \).

We briefly describe the constructs of parts and connectors below.

A part is a subset of the set of all instances of a component type. The graphical notation for a part is a box.

A region is a subset of the set of all instances of a network type. The graphical notation for a region is a box with rounded edges.

\textsuperscript{1}These constructs are similar to parts and connectors in UML 2.0, and we saw no reason to name them differently.

A connector is a set of channels. Connectors connect parts as channels connect component instances. The graphical notation for a connector is a directed or bi-directed arrow.

Regions, parts and connectors are either static or dynamic. Graphically, static constructs have a solid outline, while dynamic constructs have a dashed outline.

There are three kinds of diagrams in MEADOW. Each of these is described below.

A type diagram is a specification of the potential structure that all instances of either a component type or a network type may exhibit during their lifetime. Let \( S \) either be a static region, a static part or a static connector, and \( D \) either be a dynamic region, a dynamic part or a dynamic connector. A type diagram that (1) defines the features of \( \cdot T \) and (2) contains \( S \) and \( D \), specifies that an instance \( i \) of \( \cdot T \) must contain (1) exactly the same instances of \( S \) at all times during the lifetime of \( i:T \) and (2) a varying number of the instances of \( D \) during the lifetime of \( i:T \).

A snapshot diagram is a specification of the structure that all instances of either a component type or a network type may exhibit at one or more points in time. Let \( S \) either be a static region, a static part or a static connector. A snapshot diagram that (1) defines the features of \( \cdot T \) and (2) contains \( S \), specifies that an instance \( i \) of \( \cdot T \) must contain the specified number of the instances in \( S \) at zero or more points in time. A snapshot diagram can not contain dynamic constructs.

A views diagram structures all the diagrams that a model of a component/network type consists of. It is a set of diagram declarations and it may classify these into views. A views diagram may also contain constructs of relating declarations of snapshot diagrams in time.

4 OBJECT-ORIENTED NETWORK: ONET

We model an object-oriented network called ONet. ONet consists of three objects: two objects of class Sender and one object of class Receiver. Each sender object always has a reference to the other sender object, and one and only one sender object has a reference to the receiver at any given time. The sender objects may exchange the reference to the receiver with each other in order to send messages to it.

The model consists of four diagrams that are explained in turn.
4.1 ONet:Type

Figure 2 presents a type diagram (as defined in the top right corner of the diagram). It specifies the potential structure that all instances of network type ONet must exhibit during their lifetime.

The parts that are labeled s1:Sender and s2:Sender consist of one component instance named s1 of :Sender and one instance named s2 of :Sender, respectively. Similarly, the part labeled re:Receiver consists of one component instance named re of :Receiver. The three parts in figure 2 are all static, because the graphical notation of a static part is a box with a solid outline. A static part must always consist of the same instances during its lifetime. In the current example, this means that each instance n of :ONet, must contain s1:Sender, s2:Sender, and re:Receiver at all times during the lifetime of n.

The diagram in figure 2 contains two static connectors named s and o and two dynamic connectors labeled c:r. A static connector consists of channels that are always part of a composite component or a network as long as the components the channels connect are part of the same composite component or network. A dynamic connector, however, is a connector that consists of channels that may be created or killed during the lifetime of the component instances they connect.

The relationship of channels that a connector consists of is affected by the cardinality of the parts that the connector connects. In general, a connector c going from a part P1 to a part P2 means that ∀x ∈ P1, ∀y ∈ P2, there is a channel from component instance x to component instance y.

A connector may be directed or bi-directed. The graphical notation of a directed connector is a line with an arrowhead at one end, whereas the graphical notation of a bi-directed connector is a line with an arrowhead in both ends. A bi-directed connector is two directed connectors containing channels that forward messages in opposite directions.

The directed connector named o consists of one channel that goes from re:Receiver to the environment of the network that re:Receiver is a part of. In other words, each network n of :ONet must have a channel that goes from re:Receiver to the environment of n at all times during the lifetime of n.

The lowermost dynamic connector labeled c:r is named r, and it consists of one channel named c that goes from s1:Sender to re:Receiver. The fact that the connector is dynamic means that the channel the connector consists of may or may not be part of a network n of :ONet during the lifetime of n even if both components (s1 and re) are part of n. The fact that both dynamic connectors are equally named and consists of a channel with the same name (c), implies that only one component instance may transmit messages on channel c at any given time.

4.2 ONet:Snapshots

A snapshot diagram specifies the configuration that instances of a component type or a network type may exhibit at a point in time.

Our model of ONet consists of the two snapshot diagrams presented in figure 3. The leftmost diagram is named initial and the rightmost diagram is named step2. The name initial is reserved. A snapshot diagram with this name specifies the initial structure that all instances of a component type or a network type must exhibit upon their creation. In this example, all networks of type :ONet must exhibit the structure specified in the leftmost diagram in figure 3 upon their creation.

4.3 ONet:Views

The last of the four diagrams that the model of ONet consists of is presented in figure 4. As indicated in the top right corner of the diagram, this is a so-called views diagram. It contains the declaration of the three diagrams we have seen so far.

The arrows in the diagram specify how the snapshot diagrams are related in time. Let \( D_1 \rightarrow D_2 \) denote an arrow from diagram \( D_1 \) to diagram \( D_2 \) for a network type \( N \). \( D_1 \rightarrow D_2 \) means that a network \( n \) of \( N \) may exhibit the structure specified in
5 AD HOC NETWORK: BCS

In the following we model a network called the Battlefield Control System (BCS) on the basis of an informal description given in (Clements et al., 2001). The system is used to control the movement, strategy and operations of troops in the battlefield.

BCS consists of a commander and a number of soldiers. The commander acts as a server and the soldiers act as its clients. One of the soldiers acts as backup. Upon failure of the commander, the backup will take over as the new commander. Communication between clients and the server is only through encrypted messages sent via a radio modem.

BCS is an ad hoc network in the sense that (1) all components and channels in the network may be created or killed during computation and (2) it is dynamically reconfigurable.

We do not give a full specification of BCS, but model the scenario of commander breakdown.

5.1 BCS: Views and BCS: Type

We model the system at a logical level (we do not consider the physical level) as the network type :BCS. The three diagrams that specify the internal structure of the network instances of :BCS are declared in the views diagram presented in figure 5.

Note that three formal parameters are declared in the top left corner of the diagram. The first is a type named Rid, the second and third are the constants c and b of type $S$ (the set of all strings).

The type diagram for :BCS is presented in figure 5. All parts in the diagram are dynamic. The part that is associated with the label c:Commander, has a maximum cardinality of one and a minimum cardinality of zero. Here, this means that a network n of network type :BCS may contain zero or one instances of :Commander at any given point during its lifetime. A similar constraint applies for the part that models the backup.

As declared in the top right corner of the diagram, Rid is a type, i.e. a set of identifiers. This type is used as an identifier for the part labeled Rid:Soldier, which models the soldiers. The maximum cardinality of this part is #Rid (the cardinality of Rid), and the minimum cardinality is zero. The maximum and minimum cardinality of a part could also be determined by a multiplicity. E.g. a part labeled Rid:Soldier[3..8] would have a minimum cardinality of 3 and a maximum cardinality of 8.

5.2 BCS: Snapshots

Figure 6 presents the two snapshot diagrams that are declared in the views diagram (figure 5). The diagram named initial specifies the initial structure that a network of :BCS must exhibit upon its creation. Notice here that there is no initial connection between the backup and the soldiers.

The lowermost diagram of figure 6 specifies the network structure upon breakdown of the commander. Here, a connection is established between the soldiers and the backup as a result of the commander not being part of the network anymore. The multiplicity ([0..]) associated with the part of type Soldier, specifies that the part has a minimum cardinality of zero and a maximum cardinality of #Rid (#Rid because the upper bound of the multiplicity is not defined) at the time of breakdown. Similarly, the part of type Backup has a minimum cardinality of zero and a maximum cardinality of one at the time of breakdown.

6 MOBILE CODE NETWORK: PDANET

We model a network that is based on a framework for building context-aware applications in ubiquitous and
mobile computing settings. The goal of the framework is to offer a location-aware system in which spatial regions can be determined to within a few square feet, so that one or more portions of a room or a building can be distinguished.

The framework consists of two parts: (1) mobile agents and (2) local information servers, called LISs. The former offers application-specific services which are associated with physical entities and places. The latter provide a layer between underlying locating systems and mobile agents. Each LIS provides the agents with up-to-date information on the state of the real world, such as the locations of people, places and things, and the destinations that agents should migrate to. For a more detailed description of the framework, we refer to (Satoh, 2002).

We model a simple network called PDANet that is based on this framework. The physical components that constitute PDANet are: a sensor, a LIS, a computer associated with a tag and a personal digital assistant (PDA) also associated with a tag. The tags make it possible for the sensor to locate the physical entities (the computer and the PDA). Each tag periodically transmits a unique identifier via infrared light that can be received by the sensor. The tag associated with the computer is always within the presence of the sensor, while the tag associated with the PDA may or may not be within the presence of the sensor at a given point in time. The sensor uses a radio frequency to notify the LIS of the tags that are within the presence of the sensor at a given point in time. The LIS communicates with the computer and the PDA on the same radio frequency.

At a logical level, both the computer and the PDA each have a runtime system (the Java based mobile agent system Mobile Spaces (Satoh, 2000) for example). These runtime systems can execute a mobile agent we call app. Moreover, app moves from the runtime system on the computer to the runtime system on the PDA when both the previously mentioned tags are within the presence of the sensor.

6.1 PDANet:Views

We model PDANet as the network type :PDANet. A views diagram of :PDANet is presented in figure 7. Here, two type diagrams are declared. These are structured into two views named Physical and Logical. These diagrams define the potential structure that instances of :PDANet may exhibit as seen from two different points of view.

Three types are declared in the header of the views diagram. These types may be used in the internal structure of all the diagrams that are declared in the views diagram. “L = :MA” means that the type L equals all instances of the component type named MA. Consequently, connectors associated with the message type L, consist of channels that may forward component instances of :MA.

6.2 PDANet::Type::Physical

The type diagram that is contained in the physical view is presented in figure 8. Here the region labeled Cell models the infrared transmission radius of the sensor. The region containing comp:AH (the computer) and Tag (the tag associated with the computer) is always within this transmission radius. This region consists of an unnamed network instance of an unnamed network type (because it is not labeled). The dynamic region containing pda:AH and Tag models the fact that the PDA and its associated tag may or
may not be within the transmission radius at a given
point in time.

The connector named \( f \) of message type \( IF \) repre-
sents the infrared communication between the tags
and the sensor. Similarly the connector named \( rf \)
of message type \( RF \) represents the radio communication
between the computers, the sensor and the LIS. Both
these connectors represent connectivity at the physical
level. Furthermore, both connectors are associ-
ated with a merge-split node (its graphical notation
is a grey filled circle). A connector that is associated
with such a node contains a single shared channel that
can not be specified. These concepts have been found
in the name of a component instance, and the two parts
can be imposed. However, a minimum bound on the cardinality of process sets cannot
be specified explicitly, and SDL does not distinguish
between static and dynamic constructs.

In the following, we compare the concepts of
MEADOW with relevant concepts of state-of-the-art
graphical specification languages. A good overview
of graphical specification methods and techniques can be found in (Wieringa, 1998). Notable state-of-the-art
languages/methods for modeling structure are Spec-
fication and Description Language (SDL) (ITU-T,
2000), Unified Modeling Language (UML) (OMG,
2003), Real-time Object-Oriented Modeling (ROOM)
(Selic et al., 1994), and FOCUS (Broy and Stølen,
2001). The relevant parts of these languages/methods
which we refer to, are the constructs for structuring
agents in SDL-2000, composite structures in UML
2.0, constructs for structuring actors in ROOM, and
the graphical style in FOCUS.

ROOM separates between static and dynamic con-
structs in the specification of potential structure. The
relevant dynamic constructs are dynamic actors and
dynamic actor relationships. These are similar to, but
less expressive than dynamic parts and dynamic
connectors, respectively. This is due to the fact that
ROOM does not enable the specification of a lower
and an upper bound on multiplicity.

UML does not separate between static and dy-
namic constructs, but the construct called \( \text{part} \)
in UML is similar to dynamic part in MEADOW. That
is, UML does enable the specification of upper and
lower bound on the multiplicity in parts and the se-
manetics of this is similar to the semantics of maxi-
mum and minimum cardinality of dynamic parts in
MEADOW. UML does not have the equivalent of sta-
tic components or dynamic connectors (connectors in
UML are similar to static connectors in MEADOW).
Consequently, a specification like the one in figure
2 where dynamic connectors are used, and figure 8
where static components are used, cannot be made us-

ing the constructs of UML.

In SDL, constraints on the maximum number of
instances that a process set (similar to a component
set) may consist of can be imposed. However, a min-
imum bound on the cardinality of process sets cannot
be specified explicitly, and SDL does not distinguish
between static and dynamic constructs.

The graphical style of FOCUS does not distinguish
between static and dynamic constructs, and upper and
lower bounds on the cardinality of components sets
can not be specified. FOCUS does however, unlike the
other languages we have discussed, allow individual
instances of component sets to be named. Without
this, mobile code networks cannot be specified like it
is done in the diagram given in figure 9. Here \( \text{app:MA} \)
is the name of a component instance, and the two parts
tored \( \text{app:MA} \) may consist of the same component
instance (at different points in time).

Of all the previously discussed languages, only
UML enables the specification of snapshot structure.
However, UML (and the three other languages) does

6.3 PDANet::Type::Logical
The diagram that is contained in the logical view is
presented in figure 9. Here, the internal structure
of the two composite component instances of \( \text{AH} \) is
specified. Specifically each instance of \( \text{AH} \) contains
an unnamed instance of \( MS \) which in turn may or may
not contain \( \text{app:MA} \) at a given point in time.

The unnamed connector in figure 9 is associated
with the message type \( L \). Since this message type
equals the component type \( \text{MA} \) (as defined in figure
7), instances of type \( \text{MA} \) can be sent along the chan-
nels contained in this connector.

7 DISCUSSION AND RELATED
WORK
MEADOW does not currently have a formal seman-
tics, nor is it supported by any computerized tool.
As such, the pragmatic value of the language in it-
self is not as great as many well known languages.
The main goal of this paper is, however, to present
concepts with which to specify dynamic networks in
structural diagrams. These concepts have been found
useful in the sense that they enable the specification of
dynamic aspects in examples of real networks that can
not be expressed in other state-of-the-art languages.
The question of how useful this added expressiveness
is should ideally be addressed in empirical studies, but
this has not yet been done.
not have constructs for relating such snapshot diagrams in time.

8 CONCLUSIONS AND FUTURE WORK

We have presented the language MEADOW for specifying dynamic networks from a structural viewpoint. We have demonstrated the language in three examples addressing an object-oriented network, an ad hoc network and a mobile code network. Specification of dynamic reconfiguration is achieved through the clear distinction between snapshot diagrams of the structure that networks may exhibit at a point in time and type diagrams of the structure that networks may potentially exhibit over a period of time. Dynamic reconfiguration is modeled through (1) the construct of relating snapshot diagrams in time and (2) static/dynamic constructs that constrain the potential structure of a network.

The obvious advantage of increased expressiveness in structural diagrams is that they convey more information while maintaining a high level of abstraction. That is, without containing detailed information about execution or implementation of components. Another advantage is that constraints in structural diagrams can be used as a basis for automated model checking by checking whether the behavior of components abide to their associated constraints expressed in the structural diagrams.

In order for MEADOW to be used for simulation purposes, it must be used in combination with a language for modeling behavior such as π-calculus, STATECHARTS or (certain parts of) FOCUS for example. Hence, future work on developing constructs for specifying behavior of components, or alternatively on how to combine MEADOW with existing such languages, would be interesting.

MEADOW does not have a formal semantic definition, nor is it supported by any computerized tool, hence this is a natural direction of future work.

ACKNOWLEDGEMENTS

The research on which this paper reports has partly been founded by the Research Council of Norway through the project SECURIS (152839/220). We thank Mass Soldal Lund and Ida Hogganvik for useful feedback.
