Abstract: Previous research in the area of buyer agent strategies for choosing seller agents in ecommerce markets has focused on frequent purchases. In this paper we present a reputation based buyer agent strategy for choosing seller agent in a decentralized, open, uncertain, dynamic, and untrusted B2C ecommerce market for frequent and infrequent purchases. The buyer agent models the reputation of the seller agent after having purchased goods from it. The buyer agent has certain expectations of quality and the reputation of a seller agent reflects the seller agent’s ability to provide the product at the buyer agent’s expectation level, and its price compared to its competitors in the market. The reputation of the seller agents and the price quoted by the seller agents are used to choose a seller agent to transact with. We compare the performance of our model with other strategies that have been proposed for this kind of market. Our results indicate that a buyer agent using our model experiences a slight improvement for frequent purchases and significant improvement for infrequent purchases.

1 INTRODUCTION

Our work considers decentralized, open, dynamic, uncertain and untrusted electronic market places with seller agents and buyer agents. The seller agents sell products and the quality and the price of product varies across them. The goal for the buyer agent (hereafter referred to as the buyer) is to purchase a product from a seller agent (hereafter referred to as the seller) who meets its expectations of quality and service and to purchase it at the lowest price possible in the market. At the same time the buyer wants to reduce its chances of interacting with dishonest and poor quality seller agents. In an open market, the sellers agents (hereafter referred to as sellers) and the buyers agents (hereafter referred to as buyers) can enter and leave the market anytime. In a dynamic market the players in the market need not exhibit the same behaviour all the time; the sellers can vary the price and the quality in various transactions. Untrusted market implies there could be dishonest sellers in the market. By uncertain market we mean that the buyers can gauge the quality of the product after actually receiving the product. There could be a one time transaction between the buyer and the seller or multiple transactions between them. There is no limitation on the number of the sellers and the buyers in the market. These characteristics are typical of a traditional commerce market and hence we consider a similar environment for our electronic market.

It is not possible to pre-program an agent to operate under these conditions, or to know beforehand who the best seller for a buyer is, as new sellers are entering the market, the lowest priced seller may not necessarily be the best seller, and sellers could be lying. Agents have to be equipped with abilities to make the most rational decision based on all the information that they can gather. They should be able to learn from their past experiences.

Cohen, 2004, Vol. 2, p. 828-835), (J.M. Vidal & E.H Durfee, 1996, p. 377-384). However, as Tran (T. Tran, 2003) summarizes, the agents in (R.B. Doorenbos & Etzioni & D. Weld, 1997, p. 39-48), (B. Kruulwich, 1996, p. 257-263) are not autonomous, the agents in (A. Chavez & P. Maes, 1996), (A Chavez & D.Dreilingger & R.Guttman & P. Maes, 1997), (C. Goldman & S. Kraus & O.Shehory, 2001, p. 166-177), and (R.B. Doorenbos & Etzioni & D. Weld, 1997, p. 39-48), do not have learning abilities, the agents in (J.M. Vidal & E.H Durfee, 1996, p. 377-384) have significant computational costs, and the agents in (A. Chavez & P. Maes, 1996), (A Chavez & D.Dreilingger & R.Guttman & P. Maes, 1997), (C. Goldman & S. Kraus & O.Shehory, 2001, p. 166-177), (R.B. Doorenbos & Etzioni & D. Weld, 1997, p. 39-48), (B. Kruulwich, 1996, p. 257-263), (J.M. Vidal & E.H Durfee, 1996, p. 377-384) do not have the ability to deal with deceptive agents. Tran and Cohen’s (T. Tran & R. Cohen, 2004, Vol. 2, p. 828-835), (T. Tran, 2003) work addressed these shortcomings by developing a strategy for the buying agents using reinforcement learning and reputation modelling of the sellers. However their model builds reputation slowly and the buyer has to interact with a seller several times before the seller is considered reputable. This model works well where the buyer has to make repeated transactions with the sellers. However their model builds reputation slowly and the buyer has to interact with a seller several times before the seller is considered reputable. The performance of this model deteriorates for infrequent purchases as the buyer has to purchase several times from a seller before making its decision about the seller. When the buyer is purchasing a product on an infrequent basis it needs to quickly identify reputed sellers.

We present reputation based modelling of a seller by the buyer which can work for frequent as well as infrequent purchases in a B2C ecommerce market. We compared the performance of the buying agents using our model, reinforcement learning (J.M. Vidal & E.H Durfee, 1996, p. 377-384) and reputation based reinforcement learning (T. Tran & R. Cohen, 2004, Vol. 2, p. 828-835), (T. Tran, 2003). Our results show that the buying agents using our model improved their performance slightly for frequent purchases and showed a significant improvement for infrequent purchases, making our approach better suitable for all kinds of buyers.

2 METHODOLOGY

We consider decentralized, open, dynamic, uncertain and untrusted electronic market places with buyers sellers. The buyers’ model the sellers’ reputation based on their direct interactions with them. The buyer has certain expectations of quality and the reputation of a seller reflects the seller’s ability to provide the product at the buyer’s expectation level, and its price compared to its competitors in the market. The buyer’s goal is to purchase from a seller who will maximize its valuation of the product, which is a function of the price and quality of the product. At the same time it wants to avoid interaction with dishonest or poor quality sellers in the market. The reputation of the seller is used to weed out dishonest or poor quality sellers.

In this paper we use the following notation: Subscript represents the agent computing the rating. Superscript represents the agent about whom the rating is being computed. The information in the parenthesis in the superscript is the kind of rating being computed. For example, every time the buyer b purchases a product from the seller s, it computes a direct trust (di) rating T(b,s) of the seller s by buyer b. The trust rating of seller s by buyer b is computed as shown in equation 1.

\[
T_{(b,s)} = \begin{cases} 
\frac{q_{act} - p_{act}}{p_{max} - p_{min}} & \text{if } q_{act} \geq q_{min} \text{ and } p_{act} \geq p_{avg} \\
\frac{q_{exp} - q_{act}}{q_{exp} - q_{min}} & \text{if } q_{act} \leq q_{exp} \text{ and } p_{act} < p_{avg} \\
\frac{q_{exp} - p_{act}}{p_{max} - p_{min}} & \text{if } q_{act} < q_{exp}
\end{cases}
\]  

(1)

where q_{act} is the actual quality of the product delivered by the seller s, q_{exp} is the desired expected quality and q_{min} is the minimum quality expected by the buyer b, p_{act} is the price paid by the buyer b to purchase the product from the seller s, p_{min} is the minimum price quote, p_{max} is the maximum price quote received and p_{avg} is the average of the price quotes received by the buyer for this product.

The trust rating should be proportional to the degree the quality delivered by the seller meets the buyer’s expectations and the price paid to purchase the product. If there are two sellers, s1 and s2, who can meet the buyer’s expectation for the quality of the product, and s1’s price is lower than s2, then s1 should get a higher rating than s2. Similar to (T. Tran, 2003) and (T. Tran & R. Cohen, 2004, Vol. 2, p. 828-835), we make the common assumption that it costs more to produce a higher quality product. So when considering the price charged by a seller, if the seller meets the buyer’s minimum expectation for quality, and if the price is greater than the average price quoted, then the difference between the seller’s price and the average price quoted is weighted...
against the maximum price quoted for that product (part (a) of the equation). On the other hand if the price of the seller is below the average price (which can happen if the other sellers are trying to maximize their profits or there are too many low quality sellers) then the rating for this seller is computed based on its quality alone (part (b) of the equation). If the seller’s quality does not meet the buyer’s expectation then the difference of seller’s price and the minimum price quoted is compared to the difference between the maximum and the minimum price quoted to penalize the seller more severely (part (c) of the equation).

This model makes the assumption that the buyer \( b \) expects the highest quality and in the best case \( q_{act} \) can be equal to \( q_{exp} \) and it costs more to produce higher quality products. From the above equations it can been seen that \( T_b^{(di)} \) ranges from \([-1, 1] \). In the best case, \( b \) gets the expected quality at the lowest price and \( T_b^{(di)} = 1 \). In the worst case \( q_{act} = 0 \) and \( b \) pays the maximum price quoted and \( T_b^{(dimin)} = -1 \).

If the buyer has not interacted with the seller then \( T_b^{(di)} = 0 \) for that seller and such a seller is referred to as a new seller.

Whenever the buyer \( b \) is evaluating a list of sellers for purchase decisions it computes \( T_b^{(diarg)} \), the average rating for each seller \( s \) from its past interactions. \( T_b^{(diarg)} \) is computed as the weighted mean of its past \( n \) recent interactions.

\[
T_b^{(diarg)} = \frac{1}{W} \sum_{i=1}^{g} w_i T_b^{(di)}
\]  
(2)

where

\[
w_i = \frac{t_{uw}}{t_{uw} - t_i}
\]  
(3)

\[
w = \sum_{i=1}^{g} w_i
\]  
(4)

where \( T_b^{(di)} \) is the rating computed for a direct interaction using equation 1. Subscript \( i \) in parenthesis indicates the \( i \)th interaction. \( w_i \) is the importance of the rating in computing the average. Recent ratings should have more importance. Hence the weight of a rating is inversely proportional to the difference between the time a transaction happened \( t_i \) to the current time \( t_{uw} \).

The buyer has threshold values \( \theta \) and \( \omega \) for the direct trust ratings to indicate its satisfaction or dissatisfaction with the seller respectively. The threshold values \( \theta \) and \( \omega \) are set by the buyer and 0 > \( \omega \) and \( \theta \) and \( \omega \) are in the range \([-1, 1] \). The buyer chooses sellers whose average direct trust rating is greater than or equal to \( \theta \) and considers them to be reputable, does not choose sellers whose average direct trust rating is less than or equal to \( \omega \) and considers them to be disreputable. It is unsure about sellers whose average direct trust ratings are between \( \omega \) and \( \theta \) and will consider them again only if there are no reputable or new sellers to consider.

From the list of sellers who have submitted price bids, reputable sellers whose \( T_b^{(diarg)} \) is above the satisfaction threshold \( \theta \) are identified as potential sellers. The buyer includes new sellers into the list of potential sellers to be able to quickly identify a good seller.

The buyer’s valuation function for the product is a function of the price a seller is currently quoting and the quality that has been delivered in the past. For a seller with whom the buyer has interacted before, the quality is the average of the quality delivered in the past interactions. For a seller with whom the buyer has not interacted directly, the quality is set to the expected quality. From the list of potential sellers, the buyer chooses a seller who maximizes its product valuation function.

### 3 RELATED WORK

Vidal and Durfee’s (J.M. Vidal & E.H Durfee, 1996, p. 377-384) economic model consists of seller and buyer agents. The buyer has a valuation function for each good it wishes to buy which is a function of the price and quality. The buyer’s goal is to maximize its value for the transaction. Agents are divided into different classes based on their modelling capabilities. 0-level agents base their actions on inputs and rewards received, and are not aware that other agents are out there. 1-level agents are aware that there are other agents out there, and they make their predictions based on the previous
actions of other agents. 2-level agents model the beliefs and intentions of other agents. 0-level agents use reinforcement learning. The buyer has a function \( f \) for each good that returns the value that the buyer expects to get by purchasing the good at price \( p \). This expected value function is learned using reinforcement learning as \( f = f + \alpha (v - f) \) where \( \alpha \) is the learning rate, initially set to 1 and reduced slowly to minimum value. The buyer picks a seller that maximizes its expected value function \( f \). Our market model is extended into a more general one by having sellers offer different qualities and by the existence of dishonest sellers in the market. The buyers use the reputation of the sellers to avoid dishonest sellers and reduce their risks of purchasing low quality goods. The reputation of the sellers is learned based on direct interactions.

Tran and Tran and Cohen develop learning algorithms for buying and selling agents in an open, dynamic, uncertain and untrusted economic market (T. Tran, 2003) and (T. Tran & R. Cohen, 2004, Vol. 2, p. 828-835). They use Vidal and Durfee’s (J.M. Vidal & E.H Durfee, 1996, p. 377-384) 0-level buying and selling agents. The buying and selling agents use reinforcement learning to maximize their utilities. They enhance the buying agents with reputation modelling capabilities, where buyers model the reputation of the sellers. The reputation value varies from -1 to 1. A seller is considered reputable if the reputation is above a threshold value. The seller is considered disreputable if the reputation value falls below another threshold value. Sellers with reputation values in between the two thresholds are neither reputable nor disreputable. The buyer chooses to purchase from a seller from the list of reputable sellers. If no reputable sellers are available, then a seller from the list of non-disreputable sellers is chosen. Initially a seller’s reputation is set to 0. The seller’s reputation is updated based on whether the seller meets the demanded product value. If the seller meets or exceeds the demanded product value then the seller is considered cooperative and its reputation is incremented. If the seller fails to meet the demanded product value then the seller is considered uncooperative and its reputation is decremented. This model builds reputation slowly. So the buyer has to interact with a seller several times before the reputation of the seller crosses the threshold value. This model works well where the buyer has to make repeated transactions with the sellers, but a buyer cannot utilize this model when making infrequent purchases.

4 EXPERIMENTS AND RESULTS

For our experiments we developed a multi-agent based simulation of an electronic market with autonomous buying agents, selling agents, and a matchmaker. The sellers upon entering the market register with a matchmaker (D. Kuokka & L. Harada, 1995) regarding the products that they can supply. When a buyer wants to purchase a product, it obtains a registered list of sellers selling this product from the matchmaker and sends a message to each of the sellers in the list to submit their bids for the product \( p \). The sellers who are interested in getting the contract submit a bid which includes the price. The buyer waits for a certain amount of time for responses and then evaluates the bids received to choose a seller to purchase from.

The following parameters were set. The quality \( q \) sold across the sellers ranges from \([10, 50]\) and varies in units of 1. The buyer expects a minimum quality of \( q_{\text{min}} = 40 \). The price of a product for an honest seller is \( p_r = q \pm 10\%q \). Like Tran (T. Tran, 2003) we make the assumption that it costs more to produce high quality goods. We also make the reasonable assumption that the seller may offer a discount to attract the buyers in the market or raise its price slightly to increase its profits. Hence the price of the product is set to be in the range of 90\%-110\% of the quality for an honest buyer. A dishonest buyer on the other hand may charge higher prices. The buyer’s valuation of the product is a function of the quality and the price and for our simulation we set it as \( 3 \times \text{quality} - \text{price} \). The buyer’s valuation function reflects the gain, a buyer makes from having purchased a product from a seller. Each time a buyer purchases a product from a seller its product valuation is computed and we consider this as the buyer’s gain for having purchased from that seller.

We compared the performances of four buyers.

1. F&NFBuyer: This buying agent uses the buying strategy as described in our model. The buyer’s desired expected quality is \( q_{\text{exp}} = 50 \). The acceptable quality for a buyer is from \([40, 50]\). The non acceptable quality is from \([10-39]\). The maximum price \( p_{\text{max}} \) quoted by honest seller would be 55 and the minimum price \( p_{\text{min}} \) quoted would be 9. The average price \( p_{\text{avg}} \) would be 32. The threshold values \( \theta \) for a seller to be considered reputable and \( \omega \) for a seller to be considered disreputable values can be computed as follows:

\[
\begin{align*}
\theta &= q_{\text{exp}} - 0.1q_{\text{min}} \\
\omega &= q_{\text{exp}} + 0.1q_{\text{min}}
\end{align*}
\]

The buyer is expecting at least a quality of 40. In the worst case it can get this at the highest
price that can be charged by a honest seller which would be 44. From equation 1(a) the trust rating for that seller would be

\[
\theta = \frac{40}{50} - \frac{44}{55} = 0.581
\]

so we set \( \theta = 0.58 \). For new sellers the trust rating is set to 0. These buyers should not come under the category of disreputable sellers. So we set the threshold value for a seller to be considered unacceptable as -0.1. So \( \omega = -0.1 \).

2. Tran Buyer: - This buying agent uses the buying strategy as described in Tran and Cohen [8]. The threshold for seller to be considered reputable is set to 0.5 and for seller to be considered disreputable is set to -0.9 as described in their work.

3. RL Buyer:- This buying agent uses a reinforcement learning strategy as described for 0-level buying agent in Vidal and Durfee [9].

4. Random Buyer:- This buying agent chooses a buyer randomly.

We populated the market with 12 sellers belonging to one of the six categories with the price and quality properties as shown (two agents per category):

1. Honest Acceptable (HA): - Each seller offers a quality in the range [40-50]. The price is between 90-110% of the quality they are selling.
2. Honest Not Acceptable (HNA): - Each seller offers a quality in the range [10-39]. Their price is between 90-110% of the quality they are selling.
3. Overpriced Acceptable (OPA):- Each seller offers a quality in the range [40-50]. The price is between 111-200% of the quality they are selling.
4. Overpriced Not Acceptable (OPNA): - Each seller offers a quality in the range [10-39]. Their price is between 111-200% of the quality they are selling.

5. Inconsistent: - Each seller offers a quality in the range [10-50]. The price is between 90-110% of the quality they are selling.

6. Dishonest: - This category of sellers in their first sale to a buyer offer acceptable quality \( q \) [40-50] charging a price \( pr = q \pm 10\%q \). In their subsequent sales to that buyer they reduce the quality \( q \) to be in the range [10-25]. However their price still remains high. Price \( pr = q1 \pm 10\%q1 \) where \( q1 \) is in the range [40-50].

The data from the experiments was collected over 100 simulations. In each simulation, each buying agent conducted 500 transactions. In each transaction they purchased product \( p \) by querying the seller list from the matchmaker, obtain price quotes from different sellers and utilize their buying strategy to choose a seller. We compared the performances of the various buying agents on the following parameters.

- How long it took them to learn to identify high quality low priced sellers. We want the buying agents to identify high quality sellers offering low prices as soon as possible. If the buyer is able to identify high quality sellers quickly then the same strategy can be used when making infrequent purchases.
- The average gain as the number of purchases of product \( p \) is increased. If the average is consistently high means that the buyer is interacting with high quality sellers offering low prices most often. If the average gain is high earlier on implies that the buyer has identified high quality low price sellers quickly.

Figures 1-3 show the gain versus transactions for each type of buyer (because of space considerations we are not showing the plot of the gain vs. a random buyer, since the gain simply constantly fluctuates):
Figure 2: Gain Vs Transaction for a Tran Buyer.

Figure 3: Gain Vs Transaction for a RL Buyer.

Figure 4: Average Gain versus Number of Purchases for different buyers.
Table 1 shows the number of purchases made by a buyer from each seller type.

Acceptable quality sellers can offer qualities anywhere between 40-50. The lowest gain from purchasing from a honest seller offering at the lowest end of good quality range and charging its highest price is 76 (3*40 – 44). When the gain from purchasing from a seller is 76 and above, it means the buyer is purchasing from a high quality low priced seller. From figures 1-3 it can be seen that F&NF Buyer, Tran Buyer and RL Buyer learn although at different rates to identify high quality low priced sellers. After having learned, they consistently interact with high quality low priced sellers. This is confirmed by the fact that highest number of purchases are made from honest acceptable sellers as shown in table 1. Random Buyers never learn and that is to be expected as they are choosing sellers randomly. F&NF Buyer learns to identify high quality low priced sellers very quickly in about 15 transactions or purchases. Tran Buyers take about 60 transactions to learn and RL Buyer learns in about 250 transactions. If the buyers were to purchase the product infrequently then the F&NF Buyer strategy would work better than the RL or Tran Buyer strategy. As the number of purchases increases, F&NFBuyer still has the highest average gain with the Tran Buyer’s average gain coming very close to it at very high number of purchases.

5 CONCLUSIONS AND FUTURE WORK

We presented a model for a buyer to maintain the seller reputation and strategy for buyers to choose sellers in a decentralized, open, dynamic, uncertain and untrusted multi-agent based electronic markets. The buyer agent computes a seller agent’s reputation based on its ability to meet its expectations of product, service, quality and price as compared to its competitors. We show that a buying agent utilizing our model of maintaining seller reputation and buying strategy does better than buying agents employing strategies proposed previously for frequent as well as for infrequent purchases. For future work we are looking at how the performance of buying agent can be improved for extremely infrequent purchases.
