Keywords: Job-shop, Train Scheduling, Regular Criteria.

Abstract: A train scheduling problem in a single-track railway is studied using a mixed graph model for a job-shop with appropriate criteria. There are several performance evaluations for a train schedule. Optimizing a train schedule subtends minimizing total tardiness of the trains, minimizing the sum of train transit times, minimizing the makespan for a train schedule, etc. Since the corresponding job-shop problems with the above three criteria are NP-hard, several heuristic algorithms have been developed using different priorities based on the release times of the jobs, the job due-dates and the job completion times. Experiments on a computer were used for evaluating the quality and efficiency of the heuristic algorithms developed for appropriate job-shop problems. The release times, due-dates and completion times of the jobs have been used as input parameters (priorities) in the computer simulation to see the effect of them on the quality of the schedules with different objective functions. The efficiency of the developed heuristics was demonstrated via a simulation on a set of randomly generated instances of small and medium sizes. The computational results showed that one heuristic algorithm outperformed the other algorithms tested for two of the three objective functions under consideration.

1 INTRODUCTION

This paper addresses the problem of generating an efficient schedule of passenger and freight trains in a single-track railway. We use the terminology from (Lusby et al., 2011) for train scheduling and that from (Tanaev et al., 1994) for machine scheduling.

In the world, the railway traffic is increasing from year to year. The employment of railroads grows both for passenger and freight transportation. When the density of train moving is increasing, the train schedule becomes more difficult both as generation and control are concerned. During the last decades, a lot of new algorithms and software have been developed and published in the OR literature and in special literature in order to produce a better tool for generating an accurate and reliable train schedule.

In this paper, it is shown how one can find a train schedule which is close to an optimal one with three objective functions for a single-track railway. A possible way to achieve a proper train schedule uses job-shop scheduling (Burdeett and Kozan, 2010; Mascis and Pacciarelli, 2002; Szpigel, 1973), although job-shop problems are fairly complicated since they belong to the class of NP-hard problems (Brucker et al., 1997; Brucker et al., 2007; Tanaev et al., 1994). In order to achieve a practical size of a job-shop problem, which can be solved within a reasonable time, we propose and test several heuristic algorithms for three objective functions which are appropriate for train scheduling. In Sections 3–6, we consider a railway network provided that a pair of sequential stations can be connected by at most one single-track (a railroad section). In particular, this is the case for most railway systems in countries of the Middle East.

2 LITERATURE REVIEW

In (Zhou and Zhong, 2007), a resource-constrained project scheduling was used for a single-track timetabling problem. Both the track segments and stations were modelled as limited resources. A branch-and-bound algorithm has been developed in order to obtain a feasible train timetable with a guaranteed level of optimality. A lower bound based on Lagrangian relaxation was used to relax the segment and
station capacity constraints. A lower bound was used to estimate the least train delay. An upper bound was constructed via a beam search heuristic. In (Cai and Goh, 1994), a heuristic algorithm was developed for train scheduling in a single-track railway under the assumption that all trains moving in the same direction must have the same speed. A greedy heuristic was proposed based on a local optimality criterion in the event of a potential crossing conflict.

The paper (Liu and Kozan, 2011) was devoted to train scheduling problems when prioritized trains and non-prioritized trains are simultaneously traversed in a single-track railway. No-wait conditions arise because the prioritized trains (e.g., an express passenger train has a higher priority) should traverse continuously without interruptions. Non-prioritized trains (e.g., a freight train) are allowed to either enter the next section immediately (if it is free) or to remain in a section until the next section on the route becomes available. A generic algorithm has been developed to construct a feasible train timetable in terms of the given train order. The proposed algorithm comprises several recursively used procedures to guarantee the feasibility by satisfying the no-waiting, a deadlock-free condition, and a conflict-free constraint.

B. Szpigel (Szpigel, 1973) was the first who identified the similarities between a job-shop problem and train scheduling problems in a single-track railway. The former was solved in (Szpigel, 1973) using a branch-and-bound algorithm, where the initial linear programming problem excludes the order constraints. Branching is required if the current solution contains trains which are in a conflict (i.e., when trains turn out to be located on the same railroad section at the same time). The objective was to minimize the weighted sum of the train transit times. Computational results for 5 single-track sections and 10 trains have been reported. The same problem was considered in (Carey and Lockwood, 1995) via binary mixed integer programming similarly to that considered in (Jovanovic and Harker, 1991). The temporal constraints were identical to those used in (Szpigel, 1973). The objective was to minimize the deviation from the ideal arrival times and the departure times for the trains to be scheduled. In (Mladenovic and Cangalovic, 2007), a job-shop problem was used to solve the train scheduling problem, where a route was interpreted as follows: The route is a sequence of the facilities the train must cross from the origin to the destination. Assuming that the train trips are jobs to be scheduled, which require elements of the infrastructure as restricted resources, it was done by mapping the initial problem into a special case of a job-shop problem. In order to solve the job-shop problem, a constraint programming approach has been developed. A support for finding quickly a good schedule was offered by an original separation and a bound-and-search heuristic. To improve the time performance, a surrogate objective function was used which had a smaller domain than the actual objective function.

In (Dorfman and Medanic, 2004), a discrete-event model was used to schedule the traffic on a railway network. This model was computationally efficient and generated near optimal schedules with respect to a number of time-of-travel-related criteria. In (Burdett and Kozan, 2010), train scheduling was interpreted in terms of a job-shop problem with parallel machines. A disjunctive graph model was used in several algorithms with the makespan objective. It was demonstrated that solutions with a good quality may be obtained within a reasonable CPU-time.

3 PROBLEM SETTINGS AND TESTING

One of the main problems in the management of a railway network is the train scheduling (timetabling) problem, in which it is necessary to determine a schedule (timetable) for a set of given trains that does not violate the railway constraints. This problem has to be solved at the tactical level of the railway planning process (Lusby et al., 2011). For the case of a single-track railway, train scheduling may be interpreted as the following job-shop problems.

There are $n$ jobs $J = \{J_1, J_2, \ldots, J_n\}$ to be processed on $m$ different machines $M = \{M_1, M_2, \ldots, M_m\}$. The time $p_{ij} > 0$ needed for processing an operation $O_{ij}$ of a job $J_i \in J$ on the corresponding machine $M_k \in M$ is known. Operation preemptions are not allowed, and the machine routes $O' = (O_{i1}, O_{i2}, \ldots, O_{in})$ for the jobs $J_i \in J$ may be different. A job $J_i \in J$ is available for processing from time-point $r_i \geq 0$. The time-point $d_i$ defines a due-date for completing the job $J_i$. A machine $M_k \in M$ can process a job $J_i \in J$ at most once. So, any two operations $O_{ij}$ and $O_{ik}$, $j \neq k$, of the same job $J_i \in J$ have to be processed by different machines of the set $M$, i.e., inequality $n_i \leq m$ holds (such a problem is called a classical job-shop).

One objective is to find a schedule minimizing the sum $\gamma = \sum_{i=1}^{n} T_i$ of the tardiness times $T_i = \max\{0, C_i - d_i\}$ of the jobs $J_i \in J$. Hereafter, $C_i$ denotes the completion time of a job $J_i \in J$. According to the three-field notation $a|b|\gamma$ used for machine scheduling problems, the above job-shop problem is denoted as $J|r\mid \sum T_i$. If $\gamma = \sum_{i=1}^{n} C_i$, then this problem is denoted as $J|r\mid \sum C_i$. If $\gamma = \max_{i=1}^{n} C_i$, then it is
denoted as $J[r_i]C_{\text{max}}$.

The problems $J[r_i]\sum T_i$, $J[r_i]\sum C_i$ and $J[r_i]C_{\text{max}}$ arise in train scheduling for a single-track railway. To determine the best train schedule among those which do not violate the single-track capacities. For passenger trains, the criteria $\sum T_i$ and $\sum C_i$ are more important than $C_{\text{max}}$ while for freight trains, the criteria $C_{\text{max}}$ and $\sum C_i$ are more important than $\sum T_i$.

In a job-shop approach to train scheduling, the trains and railroad sections are synonymous with the jobs $J_i \in J$ and the machines $M_j \in M$, respectively. An operation $O_{ij}$ is regarded as a movement of a train $J_i \in J$ across a railroad section $M_j \in M$ (in the route $O'$, machine $M_j$ processes operation $O_{ij}$). The positive number $p_{ij}$ refers to the time required for train $J_i \in J$ to travel through the railroad section $M_j \in M$. The non-negative number $r_i$ denotes the departure time of train $J_i \in J$, which is given in the official train timetable. The positive number $d_i$ denotes the official arrival time of train $J_i \in J$ (a due-date for the desired completion time $C_i$ of a job $J_i \in J$ at the terminal station in the route $O'$). Note that for train scheduling the inequality $m \geq n$ usually holds.

The problems $J[r_i]\sum T_i$, $J[r_i]\sum C_i$ and $J[r_i]C_{\text{max}}$ are complicated in the computational sense since their special cases belong to the class of NP-hard problems (Tanaev et al., 1994). In order to achieve a practical size of a classical job-shop problem, which can be solved heuristically within a reasonable time, we coded a shifting bottleneck algorithm, which was originated in (Adams et al., 1988) for the job-shop problem $J[r_i]C_{\text{max}}$. However, testing the program realizing a shifting bottleneck algorithm for the problem $J[r_i]\sum T_i$ showed an unsatisfactorily large CPU-time when the number $n$ of trains was large and the number $m$ of railroad sections was no less than $n$ (Sotskov and Gholami, 2012). A simulation showed that this algorithm can handle 125 operations (e.g., 25 trains on 5 railroad sections or 5 trains on 25 railroad sections) within half an hour of CPU-time. For larger job-shops with $m \geq n$, the CPU-time grows quickly.

In Sections 4 and 5, we develop heuristic algorithms, which run faster than the shifting bottleneck algorithm providing a quality of the objective function values which is close to the delay of the schedules constructed by the shifting bottleneck algorithm.

### 4 MIXED GRAPH MODEL

The problems $J[r_i]\sum T_i$, $J[r_i]\sum C_i$ and $J[r_i]C_{\text{max}}$ described in Section 3 can be formulated using a mixed graph model $G = (Q, C, D)$ (Tanaev et al., 1994) or a disjunctive graph model (Sussmann, 1972).

Let $Q$ denote the set of operations $O_{ij}$, $J_i \in J$, $j \in \{1, 2, \ldots, n_i\}$, to be executed by the machines $M_j \in M$ and a dummy operation $O_{00}$ associated with the beginning of a schedule and $n$ dummy operations $O_{1, n_i+1}$ associated with the completion of the jobs $J_i \in J$.

Two operations $O_{ij}$ and $O_{ik}$, which have to be executed by the same machine $M_j \in M$, cannot be simultaneously processed by this machine. This restriction is presented by an edge $[O_{ij}, O_{ik}] \in D$. Two consecutive operations $O_{ij}$ and $O_{j+1}$ of the same job $J_i \in J$ are connected by an arc $(O_{ij}, O_{j+1}) \in C$, where $1 \leq j \leq n_i - 1$. The arc $(O_{ij}, O_{j+1})$ means that operation $O_{j+1}$ has to be started after the completion of operation $O_{ij}$. The processing time $p_{ij}$ is prescribed to the arc $(O_{ij}, O_{j+1}) \in C$, and the two processing times $p_{ij}$ and $p_{ik}$ are prescribed to the edge $[O_{ij}, O_{ik}] \in D$. For the dummy operation $O_{00} \in Q$, the arc $(O_{00}, O_{1})$ with the weight $r_1$ is included into the set $C$ for each job $J_i \in J$. For the dummy operation $O_{1, n_i+1} \in Q$, the arc $(O_{00}, O_{n_i+1})$ with the weight $p_{n_i}$ is included into the set $C$.

The problems $J[r_i]\sum T_i$, $J[r_i]\sum C_i$ and $J[r_i]C_{\text{max}}$ are modelled by a mixed graph $G = (Q, C, D)$. The due-dates $d_i$ are used when calculating the objective function $\sum \gamma_{ij}$ for a schedule constructed.

Since operation preemptions are not allowed, a schedule on a mixed graph $G = (O, C, D)$ may be defined as a sequence of the starting times $s_i = (s_{00} = 0, s_1, s_2, \ldots, s_{n_i}, s_{n_i+1})$ of all the operations $Q$ such that the conjunctive constraint

$$s_i^1 - s_i^j \geq p_{ij}$$

(1)

has to be satisfied for each arc $(O_{ij}, O_{ik}) \in C$, and the disjunctive constraint

either $s_i^1 - s_i^j \geq p_{ij}$ or $s_i^1 - s_i^k \geq p_{ik}$

(2)

has to be satisfied for each edge $[O_{ij}, O_{ik}] \in D$.

Using the above weighted mixed graph $G = (Q, C, D)$, to define a feasible sequence $s_i$ of the starting times, one has to replace each edge $[O_{ij}, O_{ik}] \in D$ by either the arc $(O_{ij}, O_{ik})$ with the weight $p_{ij}$ or the arc $(O_{ik}, O_{ij})$ with the weight $p_{ik}$ respecting the disjunctive constraint (2) in such a way that no circuit arises in the obtained digraph. As a result, the set of edges $D$ will be substituted by a chosen set $D_f$, the mixed graph $G = (Q, C, D)$ will be transformed into a circuit-free digraph $G = (Q, C \cup D_f, \varnothing)$, and an operation sequence for each machine of the set $M$ will be determined.

Since the cardinality of the set $Q$ is equal to $|Q| = 1 + \sum_{i=1}^{n} (n_i + 1)$, using the critical path method in $O(n^2)$ time, one can build a unique semi-automated schedule defined by the weighted digraph $G$. A schedule is called semi-automated if no operation $O_{ij}$, $J_i \in J$, $j \in \{1, 2, \ldots, n_i\}$, can start earlier without delaying the processing of some operation from the set.
5 HEURISTIC ALGORITHMS

We developed three types of algorithms denoted as Ordinal, Max-PT and Min-PT. The release times, completion times and due-dates are used as priorities in ordering the jobs \( J_i \in J \) for processing the same machine from the set \( M \). Nine heuristic algorithms of three types with three priority rules are developed.

5.1 Ordinal-algorithm

The Ordinal-algorithm generates a sequence of the operations \( O_{ij} \) on different machines of the set \( M \) in the order as they are requested for processing the jobs \( J_i \in J \). In the first iteration, the Ordinal-algorithm finds the first request (i.e., operation \( O_{1j} \)) of a job \( J_i \in J \) for the machine \( M_i \in M \) processing operation \( O_{1j} \). Then, depending on which priority rule is used, the Ordinal-algorithm computes either the release time or the completion time or the due-date as the priority of operation \( O_{1j} \). For example, let the Ordinal-algorithm use the release time of operation \( O_{1j} \) as its priority. Then the algorithm compares the release time \( r_{1j} \) of operation \( O_{1j} \) with the release times of all operations \( O_{ij} \) of the other jobs \( J_j \in J, i \neq j \), on the same machine \( M_i \in M \) processing operation \( O_{ij} \). If the release time \( r_{1j} \) is smaller than the release time of the operations of the other jobs on the same machine \( M_i \in M \), then an arc starting from operation \( O_{1i} \) and ending in operation \( O_{jk} \) has to be added to the digraph \((Q, C, 0)\). Otherwise, the symmetric arc \((O_{jk}, O_{1i})\) has to be added to the digraph \((Q, C, 0)\).

The release time \( r_{uv} \) denotes the earliest start time of operation \( O_{uv} \) which can be computed due to the recursion \( r_{uv} = \max\{r_{ij} + p_{ij}\} \), where the maximum is taken over all operations \( O_{ij} \in Q \) preceding operation \( O_{uv} \) in the digraph already constructed. The release time of the source operation \( O_{00} \) is equal to zero.

The above procedure is repeated for the second job request (iteration 2), then for the third job request (iteration 3) and so on until all machine requests have been satisfied. We called this version of the algorithm as Ordinal-SRT (from Shortest Release Time).

The other two versions of the Ordinal-algorithm based on either the completion time priority or the due-date priority are called Ordinal-SCT (Shortest Completion Time) and Ordinal-SDD (Shortest Due-Date), respectively.

5.2 MaxPT-algorithm

The MaxPT-algorithm (Maximum Processing Time) tends to schedule first the jobs that need more processing time on all machines \( M_u \in M \).

In the first step, the MaxPT-algorithm calculates the sum of the processing times (total processing time) of all operations \( O_{ij}, j \in \{1, 2, \ldots, n_i\} \), for each job \( J_i \in J \). Before scheduling, the maximum sum of the processing times of a job \( J_i \in J \) is equal to the length of a critical path in the digraph \((Q, C, 0)\).

The MaxPT-algorithm sorts the jobs \( J \) in non-increasing order of their total processing times and selects a job with the maximum total processing time to be processed next. The MaxPT-algorithm starts to process the first request (operation \( O_{1i} \)) of the job \( J_i \) with maximum total processing time, then the second request of the same job and so on until the last request of job \( J_i \). At each operation, the MaxPT-algorithm computes one of the three priorities (either the release time, the completion time or the due-date) depending on the version of the algorithm. The chosen priority is compared with those of all operations of the other jobs on the same machine \( M_u \). Then either the arc \((O_{1i}, O_{jk})\) or the arc \((O_{jk}, O_{1i})\) is added to the digraph \((Q, C, 0)\) depending on the larger priority of job \( J_i \) or job \( J_j \). The added arc defines the order of processing the jobs \( J_i \) and \( J_j \) on machine \( M_u \).

Then the MaxPT-algorithm repeats the same procedure for the other jobs that are sorted by non-increasing sums of their processing times. We call this version of the algorithm which uses the release time as priority as MaxPRT-algorithm (Maximum Processing Time, Release Time).

The MaxPTCT-algorithm (Maximum Processing Time and Completion Time) is another version that compares the job completion times as priorities, and the MaxPTDD-algorithm (Maximum Processing Time, Due-Date) compares the due-dates as priorities.

5.3 MinPT-algorithm

The MinPT-algorithm (Minimum Processing Time) is basically similar to its counterpart, the MaxPT-algorithm but in contrast to the latter one, the MinPT-
algorithm schedules first the job $J_i \in J$ that needs the smallest total processing time on all machines $M$.

The MinPT-algorithm sorts the jobs in non-decreasing order of their total processing times and then schedules the jobs on each machine $M_u \in M$ in non-decreasing order of the corresponding priorities.

The three versions of the MinPT-algorithm are the MinPTRL-algorithm (Minimum Processing Time, Release Time), the MinPTCT-algorithm (Minimum Processing Time, Completion Time) and the MinPTDD-algorithm (Minimum Processing Time, Due-Date).

6 COMPUTATIONAL RESULTS

Three versions of the three types of algorithms (Ordinal, Max-PT and Min-PT) have been coded in Borland Delphi. For the simulation, a laptop computer with the following specification has been used: Intel, coreTM 2 Duo, CPU T6400, 2.00 GHz and 2GB Internal Memory, Windows 7, Ultimate 32 bit.

We were interested in investigating experimentally the effect of choosing different types of algorithms and different priorities for the three objective functions. We randomly generated job-shop problems of size $n \times m$, where $n = m \in \{5, 6, \ldots, 12\}$ to see the effect of these algorithms on different objective functions for job-shop problems.

First, we compared the makespan objective function for randomly generated problems $J \mid r_i \mid C_{\text{max}}$ of different size $n \times m$, where $n = m$. We compared the makespan values obtained by the nine algorithms developed for instances with the same input data. Each series includes 10 randomly generated instances. The results are presented in Fig. 1, which shows that the quality of a schedule obtained by the algorithms generally depends on the input data, but both the OrdinalSCT-algorithm and the OrdinalSRT-algorithm slightly outperform the other algorithms for the makespan criterion.

In the next experiments, the nine algorithms were used to solve heuristically the job-shop problems with the objective function $\sum C_i$. Figure 2 shows that the OrdinalSCT-algorithm provides schedules with the best quality among the algorithms tested.

In the last experiments, we evaluated the objective function $\sum T_i$. Figure 3 shows that the OrdinalSCT-algorithm again provides schedules with the best quality among the algorithms tested.

</table>

In Table 1, the CPU-time taken by the nine algorithms to solve heuristically different job-shop prob-
problems are given. For all randomly generated problems of size \( n = 5 = m \) and \( n = 6 = m \) tested, the CPU-time was less than 1 s.

7 CONCLUSIONS

The problem of finding an optimal train schedule includes several criteria. We considered three of them and developed nine heuristic algorithms to solve the corresponding job-shop problems. We coded different variants of heuristic algorithms and compared three parameters for job-shop scheduling to find suitable heuristic algorithms for three objective functions.

The simulation showed that the OrdinalSCT-algorithm generates a good schedule to minimize the makespan, the sum of job completion times and the sum of job tardiness. It was shown that the use of a more complicated algorithm (like the shifting bottleneck one) for solving train scheduling problems needed more CPU-time for the case when \( m \geq n \) with only a slight improvement of the objective function values.

For future research, we recommend to compare more parameters for those objective functions appropriate for train scheduling. Note that the OrdinalSCT-algorithm may be generalized to the weighted objective functions \( \sum w_i T_i \) and \( \sum w_i C_i \) allowing a scheduler to take into account different priorities of the trains.
