Keywords: Incident Detection, Loop Detectors Systems, Traffic Interruptions, Semi-Supervised, Data Mining.

Abstract: Detection of traffic interruptions (caused by vehicular breakdowns, road accidents etc.) is a critical aspect of managing traffic on urban road networks. This work outlines a semi-supervised strategy to automatically detect traffic interruptions occurring on arteries in urban road networks using high resolution data from widely deployed fixed point sensors (inductive loop detectors). The techniques highlighted in this paper are tested on data collected from detectors installed on more than 300 signalized intersections.

1 INTRODUCTION

Managing traffic incidents is one of the crucial activities for any traffic management center. These incidents are non-recurrent, may arise due to different causes like traffic accidents, vehicle breakdowns, debris etc. and cause congestion. It is worth noting that not all accidents (e.g. a fender-bender) result in interruptions. From a traffic management perspective, it is more important to detect significant interruptions rather than accidents. Further, this should be done in real-time so that proactive actions can be used for mitigation. Broadly, we define an interruption to be any time period where the amount of traffic is significantly lower than normal traffic for a significant period of time. The focus of this study is in detecting these events of interest from inductive loop detectors installed at signalized intersections. While direct and manual traffic management center (TMC) monitoring has been adequate for previous years, many TMCs have had limited operational use of automatic incident detection techniques. This is due to these techniques' high rates of false alarms, complex calibration, and low detection rates (Williams and Guin, 2007). In fact, many automatic incident detection algorithms perform poorly in the real world, compared to simulated traffic environments (Parkany and Xie, 2005) (and please see Section 2 for more details).

Our goal in this paper is to use loop detector data for detecting traffic interruptions. Loop detector data are now widely available to traffic management personnel. Additionally, with new ATSPM based systems, such data is available at high frequency (10 Hz) and with low latency. Hence, the utilization of this data for determining traffic interruptions can have wide applicability and can be used in conjunction with other systems based on human reporting or with probe-based systems. Previous work using loop detector data is generally limited to simulation or small datasets (Section 2). In our work, we utilize 6 months of data for 300 intersections to demonstrate the usefulness of our method. This dataset is roughly 700 GB in size. We believe that it is the first study that uses fine grain (10Hz) ATSPM data for a large geographical region and over a long duration of time.

As mentioned, we seek to design algorithms to detect traffic interruptions in a relatively unsupervised fashion. We define traffic interruption as a significant, contextual and nonrecurring change observed in a combination of the following parameters: the amount of deviation of traffic volumes from predicted volumes and the duration for which the actual traffic volume deviated from the predicted volume. The first step in this process is to analyze and pre-process raw data gathered from fixed-point sensors or detectors (Section 3). Once the data has been processed, the next step in the pipeline is quantifying what an interruption is and also labeling said traffic interruptions (Section 4). The third step is to develop algorithms for predicting the labeled interruptions (Section 5). If the data is available in real-time with as low a latency as practical, this considerably aids our effort. We list three major contributions of our work:

1. Labeling data is a major challenge for big data applications since interruption ground truth is generally not available. We provide a rigorous definition and mechanism for automatically labeling events of interest (EOI), i.e. large traffic reductions for long periods) from historical data.

- 2. We develop a time-series based analysis system for detecting if an event of interest has occurred. This uses traffic information from recent time periods as well as historical data (from similar time periods on previous days or weeks) to predict if an event of interest—defined as a long traffic interruption—has occurred. Whether or not an EOI has occurred depends on a key parameter the duration of time after reduction in traffic at a single detector. This has an impact on the overall accuracy (in terms of false positives and false negatives). In particular, we find that waiting for 60 to 90 seconds after a significant reduction in traffic is reasonable to determine EOIs with high accuracy and low latency.
- 3. We perform a Spatio-temporal analysis of all EOIs to determine if there are hotspots (i.e. intersections with a large number of consistent EOIs) and spatial relationships (two EOIs occurring at neighboring intersections within a small time frame). This analysis shows that most of the EOIs are limited to around 10 (out of 300) intersections and roughly 5% of all EOIs are spatially correlated.

All of our methods are evaluated on six months of data collected from Seminole County, Florida for 300+ intersections.

2 RELATED WORK

The existing literature pertaining to incident detection can be broadly classified as follows:

- 1. Traditional systems which rely on inductive loops and video cameras for vehicle detection.
- 2. Probe-based systems (GPS data from fleets of vehicles like NavTech or HERE data).
- 3. Human reporting systems like calls to traffic management centers or the use of social media platforms (like twitter).

There is also some work on using a combination of multiple data sets. Most of the existing research in automatic incident detection is focused on freeways and or uses simulated data. The basic idea behind these approaches is that if an incident occurs, there would be a significant decrease in the occupancy at the downstream detectors and increase in occupancy at upstream detectors (Ahmed and Hawas, 2012), (Lin and Daganzo, 1997), (Lee and Taylor, 1999). Urban road networks with a high density of signalized intersections behave differently from freeways due to the influence of traffic signals, pedestrian crossings, etc. Designing algorithms for incident detection on arterial roads can hence be more challenging as compared to doing the same for freeways. In (Jeong et al., 2011; Teng and Qi., 2003; Jin et al., 2002; Lin and Daganzo, 1997), incident detection models for freeways/highways are presented. Most of these methods rely on detecting changes in the free-flowing state of traffic and use thresholds for space-time detector occupancy driven by historical trends. Incidents are detected by comparing current occupancy or speed value with the derived thresholds.

There is an extensive body of research (Balke et al., 1996; Mouskos et al., 1999; Yang et al., 2017; Park and Haghani, 2016) on incident detection using probe-based systems. The advantage of probe data over fixed detector data is that probe data cover longer sections of the road which can also be used to detect secondary incidents (Yang et al., 2017; Park and Haghani, 2016). But these algorithms highly depend on the penetration rate of the probe car and confidence level of the data. Also, algorithms based on human reporting systems make use of sources like Twitter, phone calls, Waze etc. These methods are highly dependent on the availability of such data. This data is generally sold by companies and can be expensive. In (Gu et al., 2016), the authors presented methods to mine tweet texts and extract information related to incidents. The focus of our work is on using ground sensors at intersections: this data is freely available to transportation agencies and is routinely collected. Also, our focus is on detecting traffic interruption using sensor data (detector data) from road arteries. Since the traffic patterns on arterials are significantly different from highways, the problem is significantly more challenging.

Existing research on incident detection on arterials (Ahmed and Hawas, 2012; Lingras and Adamo, 1996) relies on simulated data (and accidents) or assumes the availability of ground truth (either using simulations or labeling). Due to this, many automatic incident detection algorithms perform poorly in realworld scenarios when compared to simulated environments (Parkany and Xie, 2005). Moreover, developing an incident data-set with start and end times can be tedious and requires manual investigation by TMC personnel. Taking into account the issues highlighted above, this work focuses on detecting traffic interruptions based on real, fixed point sensor data (detector data) collected from signalized intersections and detectors on urban road networks. In the next section, we focus on the data processing needed for nearrealtime incident detection. Due to the real-world focus, we believe that the results presented in this paper can be translated into practice.

3 DATA PREPROCESSING

Traffic signal controller logs and the derived Automated Traffic Signal Performance Measures (AT-SPM) datasets are obtained from modern traffic intersections. Inductive loop detectors-installed on the intersection-collect vehicular data at a frequency of 10 Hz. This data from controller logs has four fields: Intersection name, Timestamp, Event code and, Event parameter. The event code specifies the type of event that was captured, for example, event code 81 indicates a vehicle departure. Event parameter identifies the particular detector channel or phase in which the event was captured. This data also comes with a metadata file, which contains additional information about each detector such as location (the phase to which the detector belongs), geo-coordinates, street name, intersection name, etc. Raw controller logs, when combined with this meta-data, can help us make meaningful observations about the intersection. Figure 1 shows a table with a sample of ATSPM controller logs.

Figure 1: Table with Raw Event Logs from Signal Controllers. Most Modern Controllers Generate This Data at a Frequency of 10 Hz.

We use raw controller log data to construct the time series of arrival volumes aggregated over each cycle for each detector and on each approach. We summarize the data pre-processing steps below:

- 1. We remove intervals of data where detectors are broken/not reporting any data for a significant amount of time on some days.
- 2. We remove intervals of data where the cycle length is less than a second.

We used standard software stacks (python multiprocessing packages) to process data for several intersections simultaneously on a 54 core CPU (and with an efficient implementation). The processing times are as follows: 5 minutes for one week of data from 300+ intersections on a machine with 54 cores and 256GB RAM. Thus, the computational requirements are sufficient for implementation in near real-time scenarios.

	Timestamp	Arrivals	cycle length	Detectorid	Signalid	Approachid	Phase

Figure 2: Processed Representation of the Raw Data from Figure 1. We Compute Arrival Volumes Using Techniques Presented in section 3.

The time series of arrival volumes for each detector is constructed by aggregating vehicle detections between two successive green-phase start times.

Figure 2 shows a sample of processed time series data with the following attributes: Timestamp (cycle start time), Arrivals (number of arrivals in this cycle), cycle_length (cycle length in seconds).

4 LABELING INTERRUPTIONS

In order to be able to reliably predict events of interest, we first need a method of labeling such events and furthermore, we need to detach the labeling mechanism from the event prediction algorithm. This is now described.

Traffic interruptions are registered in the controller logs—as long as we know where to look. But, not every interruption is a major one. A *large* traffic interruption—and to be clear, we are not interested in small interruptions—is defined based on two parameters:

- The magnitude of deviation (percentage reduction) of observed traffic volumes from predicted volumes. This is measured in terms of the percentage reduction of the actual traffic volume vs. the predicted value. Common sense dictates that greater the deviation, the larger the interruption.
- 2. The duration (in seconds) for which the actual traffic volume is less than a *baseline* predicted volume. Again, a big duration heralds a large interruption.

Let Y denote the percentage reduction of volume and T denote the time (in seconds) of the interruption. Events are therefore characterized in this twodimensional summarization space.

Recall that we need a baseline prediction method which gives us *normal* expected volumes of traffic.

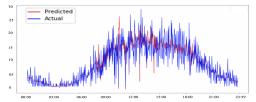

Figure 3: Actual and Predicted Volumes Vs Time for a Period of 24 Hours, and a Single Detector Showing Predicted Volumes Are Largely Consistent with Actual Traffic Patterns.

To achieve this, we merely look at the differences between arrival volumes (in recent cycles) and historical arrival volumes from similar time periods from previous days and/or weeks. The baseline predictor uses a simple method to generate traffic interruptions based on the time series data generated from arrival volumes. We found that a simple baseline predictor works well in practice and that our approach is not terribly sensitive to the choice of method. In other words, any common sense approach that yields large traffic interruptions will work in this setup.

We use a variation of non-local means as the baseline predictor. Since arrival volumes at any given time are highly dependent on cycle length and immediately preceding traffic volumes, we use the *arrivals rate* rather than arrival volumes in the predictor. Let V_i and T_i correspond to the number of arrivals and the duration of cycle *i* respectively. Then the arrival rate, X_i , is defined as $X_i = \frac{V_i}{T_i}$. The prediction algorithm finds a (linear) function that computes the arrival rate for the current cycle using previous cycles from the same day and historically relevant cycles from previous periods. Our model for *f* is

 $X_t = f(X_{t-1}, X_{t-2}, \dots, X_{t-k}, Y_{t-k}, \dots, Y_{t+k}),$

where X_i and Y_i correspond to arrival rates from the current day and historical data respectively. Expected arrival volumes (baseline) can now be computed using the arrival rate multiplied by cycle length.

Figure 3 shows that predicted volumes are in line with actual traffic volumes in this case. Figure 4 shows an example of an event where there is a significant deviation of traffic volumes from predicted volumes (both in amount and duration). In Figure 4, we see that the actual traffic volume deviated from the one predicted for a long period of time. We are interested in interruptions where the percentage reduction in volume, as well as the length of interruption are significant as shown in Figure 4.

It is worth noting that we are only interested (in this paper) when the volume in the cycle is less than the baseline, with such events henceforth referred to as dips. Each dip, as mentioned previously, is param-

eterized by its amount (Y) and duration (T). The scatter plot of these dips is a two-dimensional event space whose probability distribution can be estimated from a simple 2D histogram. We generated all the traffic interruptions using Algorithm 1.

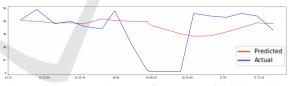

Figure 4: An Example Event of Interest Which Shows Significant Deviation of Traffic Volumes from Predicted Volumes(Amount and Duration).

The matrix in the figure 5 shows frequencies for different interruptions based on average reduction in volume (along the rows), and duration (along the columns). This distribution suggests a tripartite distinction which we adopt: central (green), borderline (yellow) and discards (red) as shown in Figure 5. The 2D histogram also suggests natural thresholds on volume reduction and duration which can be adopted to discard normal behavior while only keeping the central and borderline behaviors.

In the remainder of the paper, we use thresholds of **70**% for volume reduction and **500 seconds** for duration with these choices vetted by traffic engineers as being reasonable for this study. These result in traffic interruptions of reasonably long duration while being relatively infrequent but severe enough to require addressing. Clearly, such thresholds can be fine tuned by traffic engineers based on their requirements.

In the next section, we present our methodology to predict events of interest (EOI) with the goal of the predictive algorithm being the capture of most of the events within the bounding box and perhaps some borderline events while ignoring most if not all the non-events outside the borders.

5 PREDICTING INTERRUPTIONS

In this study, we assume that the data is being streamed in real time for all the detectors on each intersection. The preprocessing algorithm described in Section 3 is used to compute per cycle volumes in real-time. This information and previous cycles (and historical data) are then used to determine if an EOI has occurred. Clearly, for the approach to be useful, this determination has to be done as soon as possible while minimizing the false positives and false negatives. The predictive algorithm presented here takes the real-time requirement into consideration.

We present a brief outline of the approach. Since arrival volumes in cycles considerably vary, we use *cumulative volumes* instead. Then cumulative volumes from the present cycle are compared to previous and historically relevant cumulative volumes. The comparison, in turn leads to a decision criterion that is scored in terms of true and false positives (using the 'central' and 'borderline' labels from the previous section).

The first step of this process is to only consider cycles

if the current volume is smaller than the predicted volume. If this condition is met, we say that a trigger has occurred and we construct the following cumulative curves:

- Curve 1 (in red) starting from the beginning of the previous cycle as shown in Figure 7).
- Curve 2 (in blue) corresponds to recent normal cycles
- Curves 3,4,5 (in green) are cumulative arrival curves for the same time interval as in curve 1 from cycles based on historical data from the same time of the day and day of the week.

Now, our goal is to see how much these cumulative volumes differ. For example, in Figure 6(a) for an event of interest, the current cumulative curve is different from those of normal cumulative curves, whereas, for an event not of interest, the current cumulative curve is similar to some of the normal cumulative curves in Figure 6(b). Based on our analysis of many such cases, we find that the following features are highly predictive of an EOI

- Feature1: Slope of Current the Cumulative Curve(m1). Slope of the current curve from crossover point. Crossover point as shown in Figure 7 is the point where curve 1 and curve 2 intersect.
- Feature2: Angle between the Current Cumulative Curve and Historical Curves(m2). This is taken as the second maximum of the angle between curve 1 and curves 2,3,4,5.

To determine these two features, the duration of the curves to be considered after the trigger point is also an important parameter. As seen in Figure 7, after the crossover point, the degrees of dissimilarity between the current cumulative curve and the normal cumulative curves increase with time for an EOI. So with an increase in wait time after the trigger, the slope of the current cumulative curve decreases while the angles between the current cumulative and the normal curves increase thus making an EOI easier to detect.

Arrival volumes per unit time are variable across all the detectors so we divide the detectors into three sets - high volume detectors, medium volume detectors and low volume detectors. The thresholds for capturing events of interest will be different for each set as the magnitude of features depends on arrival rates. For each detector we compute arrivals per unit time during the day time for 30 days and divide the detectors based on this ratio. We perform the following experiments to see the distribution of events by using different thresholds for feature 1, feature 2 and wait

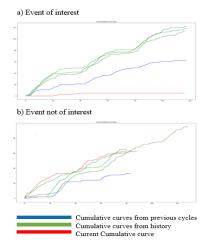

Figure 6: This Figure Shows the Difference between an Event of Interest and Event Not of Interest. We Plot Cumulative Arrival Volumes Vs Time.

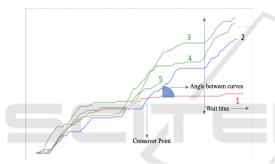

Figure 7: Cumulative Curves of Arrival Volumes Vs Time. We Use These Curves to Construct Our Feature Set.

time. For each set of detectors, we compute the distribution of events captured using different thresholds for feature 1, feature 2 and for different wait times after the trigger. This is an attempt to determine thresholds for the features in order to capture events of in-

Thresholds (High Volume Detectors) 60 Sec, 90 Sec, 120 Sec after the Trigger. This Justifies That by Waiting More Time after the Trigger, We Capture Less Events That Are Not of Interest.

terest.

Figure 8 shows the distribution of events captured for different thresholds and wait times 60 sec,90 sec, 120 sec after the trigger for high volume detectors. We can see that the number of captured events that are not of interest decrease with an increase in wait time for the same set of thresholds. This suggests that by waiting more time after the trigger, we capture fewer events that are not of interest. Also, the number of events captured that are not of interest decreases with an increase in m2 and a decrease in m1 but with the trade-off is that we miss some of the events of interest.

Figure 9 shows a comparison of the overall distribution of events vs events captured when *feature* 1(m1) < 0.09 and feature 2(m2) > 0.7, for wait times 90 sec after the trigger, for high volume de-

for different wait times after the trigger do

Figure 9: Events Captured for M1 < 0.09 and M2 > 0.7 for Wait Time 90 Sec after the Trigger. 92% of the Events of Interest, 35% of Border Events, a Minute Percentage of Events Not of Interest Were Captured. (High Volume Detectors).

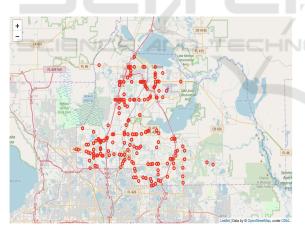

Figure 10: Locations of All the Events of Interest Generated from Nov 2018 to Apr 2019. This Plot Shows That Events Occur More Frequently at Some Intersections When Compared to Others.

tectors. For this set of thresholds(m1, m2, wait time), 92% of the events of interest, 35% of border events, a minute percentage of events not of interest were captured.

Figure 11: Locations of All the Events of Interest Generated for Each Month Separately from Nov 2018 to Apr 2019. This Plot Shows the Temporal Consistency of Some Intersections.

Figure 12: Figure Showing an Intersection Where the EOI Are Occurring Consistently over the Months of January, February, March and April.

6 SPATIO-TEMPORAL ANALYSIS OF EVENTS

We also analyze the events of interest with the goal of discovering human-understandable spatial or temporal patterns. Figure 10 shows plot the of locations of all the Events of Interest. Each red marker on the map indicates the location of the intersection where an event occurred. From the plot we can see that events are occurring more frequently at some intersections.

6.1 Temporal Patterns

The onus is on temporal pattern discovery to determine coherent activities at intersections over the period of a month. This requires the visualization of locations of EOI separately for each month. In these plots, the size of the marker is directly proportional to the number of events occurring at that particular intersection. We see from Figure 11 that at some intersections, EOIs occur consistently each month. Figure 12 shows an example of an intersection where the EOI occurs consistently over the months of January, February, March and April. The payoff from temporal pattern discovery is the highlighting of problematic intersections in this manner.

Figure 13 shows a set of intersections where interruptions are occurring consistently every month. At these intersections, total number of EOI occurred is greater than 20 and an EOI occurred at least 5 out of 6 months.

6.2 Spatial Patterns

Spatial pattern discovery complements the earlier case of temporal patterns. Here, we seek to determine the impact of EOIs at one intersection on a nearby one. The first step in this process is to derive the network topology. For each intersection, we derive a set of intersections that are neighbors based on spatial proximity. The second step is to analyze the co-occurrences of interruptions in the neighboring intersections (henceforth termed secondary interruptions). With this analysis in place, we find that 52 out of 900 events were coincident with—and thus possibly caused—an interruption in neighboring intersections.

signalid	count_nov	count_dec	count_jan	count_feb	count_mar	count_apr	total	no_of_months

7 CONCLUSIONS

The focus of this work is in the detection and prediction of traffic interruptions without the need for labeled data (from police reports and the like). After first defining events of interest corresponding to traffic interruptions using large deviations of traffic volumes and the build-up of significant delays, we constructed an event prediction approach to discover these interruptions from signalized intersection datasets. The approach-using time series analysisexamined (cumulative) approach volumes at intersections and at specific time points and compared them to historical (cumulative) approach volumes at similar time points (hour of the day and/or day of the week). This proved capable of predicting the occurrence of events of interest with high accuracy. Finally, we performed a spatio-temporal analysis of the EOIs to find recurrent patterns in the said events in order to obtain human-understandable summarizations of traffic interruptions. Our immediate future work will focus

on including police reports and labeled EOIs within this framework.
