Keywords: Stacked Autoencoder, Deep Learning, Feature Learning, Effective Weight Initialisation.

Abstract: This paper investigates deep classifier structures with stacked autoencoder (SAE) for higher-level feature extraction, aiming to overcome difficulties in training deep neural networks with limited training data in high-dimensional feature space, such as overfitting and vanishing/exploding gradients. A three-stage learning algorithm is proposed in this paper for training deep multilayer perceptron (DMLP) as the classifier. At the first stage, unsupervised learning is adopted using SAE to obtain the initial weights of the feature extraction layers of the DMLP. At the second stage, error back-propagation is used to train the DMLP by fixing the weights obtained at the first stage for its feature extraction layers. At the third stage, all the weights of the DMLP obtained at the second stage are refined by error back-propagation. Cross-validation is adopted to determine the network structures and the values of the learning parameters, and test datasets unseen in the cross-validation are used to evaluate the performance of the DMLP trained using the three-stage learning algorithm, in comparison with support vector machines (SVM) combined with SAE. Experimental results have demonstrated the advantages and effectiveness of the proposed method.

1 INTRODUCTION

In recent years, deep learning for feature extraction has attracted much attention in different areas such as speech recognition, computer vision, fraud detection, social media analysis, and medical informatics (LeCun et al., 2015; Hinton and Salakhutdinov, 2006; Najafabadi et al., 2015; Chen and Lin, 2014; Hinton et al., 2012; Krizhevsky et al., 2012; Ravi et al., 2017). One of the main advantages of deep learning due to the use of deep neural network structures is that it can learn feature representation, without separate feature extraction process that is a very significant processing step in pattern recognition (Bengio et al., 2013; Bengio, 2013).

Unsupervised learning is usually required for feature learning such as feature learning using restricted Boltzmann machine (RBM) (Salakhutdinov and Hinton, 2009), sparse autoencoder (Lee, 2010; Abdulhussain and Gan, 2015), stacked autoencoder (SAE) (Gehring et al., 2013, Zhou et al., 2015), denoising autoencoder (Vincent et al., 2008, Vincent et al., 2010), and contractive autoencoder (Rifai et al., 2011).

For classification tasks, supervised learning is more desirable using support vector machines (Vapnik, 2013) or feedforward neural networks as classifiers. How to effectively combine supervised learning with unsupervised learning is a critical issue to the success of deep learning for pattern classification (Glorot and Bengio, 2010).

Other major issues in deep learning include the overfitting problem and vanishing/exploding gradients during error back-propagation due to adopting deep neural network structures such as deep multilayer perceptron (DMLP) (Glorot and Bengio, 2010; Geman et al., 1992).

Many techniques have been proposed to solve the problems in training deep neural networks. Hinton et al. (2006) introduced the idea of greedy layer-wise pre-training, Bengio et al. (2007) proposed to train the layers of a deep neural network in a sequence using an auxiliary objective and then “fine-tune” the entire network with standard optimization methods such as stochastic gradient descent. Martens (2010) showed that truncated-Newton method has the ability to train deep neural networks from certain random initialisation without pre-training; however, it is still
inadequate to resolve the training challenges. It is known that most deep learning models are incapable with random initialisation (Martens, 2010, Mohamed et al., 2012, Glorot and Bengio, 2010b, Chapelle and Erhan, 2011).

Effective weight initialisation or pre-training has been widely explored for avoiding vanishing/exploding gradients (Yam and Chow, 2000, Sutskever et al., 2013, Fernandez-Redondo and Hernandez-Espinoza, 2001, DeSouza, 2016, Sodhi et al., 2014). Using a huge amount of training data can overcome overfitting to some extent (Geman et al., 1992). However, in many applications there is no large amount of training data available or there is insufficient computer power to handle a huge amount of training data, and thus regularisation techniques such as sparse structure and dropout technique are widely used for combating overfitting (Zhang et al., 2015, Shu and Fyshe, 2013, Srivastava et al., 2014).

This paper investigates deep classifier structures with stacked autoencoder, aiming to overcome difficulties in training deep neural networks with limited training data in high-dimensional feature space. Experiments were conducted on three datasets, with the performance of the proposed method evaluated by comparison with existing methods. This paper is organized as follows: Section 2 describes the basic principles of the stacked sparse autoencoder, deep multilayer perceptron and the proposed approach. Section 3 presents the experimental results and discussion. Conclusion is drawn in Section 4.

2 STACKED SPARSE AUTOENCODER, DEEP MULTILAYER PERCEPTRON, AND THE PROPOSED APPROACH

2.1 Stacked Sparse Autoencoder

An autoencoder is an unsupervised neural network trained by using stochastic gradient descent algorithms, which learns a non-linear approximation of an identity function (Abdulhussain and Gan, 2016, Zhou et al., 2015, Zhang et al., 2015, Shu and Fyshe, 2013). Figure 1 illustrates a non-linear multilayer autoencoder network, which can be implemented by stacking two autoencoders, each with one hidden layer.

A stacked autoencoder may have three or more hidden layers, but for simplicity an autoencoder with just a single hidden layer is described in detail as follows. The connection weights and bias parameters can be denoted as

\[ w \in \mathbb{R}^{k \times k} \]

where \( w \) is the encoding weight matrix, \( b_1 \in \mathbb{R}^k \) is the encoding bias vector, \( b_2 \in \mathbb{R}^N \) is the decoding bias vector.

For training an autoencoder with sparse representation, the learning objective function is defined as follows:

\[ J_{\text{sparse}}(W) = \frac{1}{2m} \sum_{j} \left\| x - \hat{y} \right\|^2 + \frac{\lambda}{2} \| W \| + \rho \sum_j (p \hat{p}_j) \]

where \( p \) is the sparsity parameter, \( \hat{p}_j \) is the average output of the \( j \)th hidden node, averaged over all the training samples.
samples, i.e.,
\[ \hat{p}_j = \frac{1}{m} \sum_{i=1}^{m} h_{ij} \]  
(4)
and \( \lambda \) is the coefficient for \( L_2 \) regularisation (weight decay), and \( \beta \) is the coefficient for sparsity control that is defined by the Kullback-Leibler divergence:
\[ KL(p \| \hat{p}_j) = p \log \frac{p}{\hat{p}_j} + (1-p) \log \frac{1-p}{1-\hat{p}_j} \]  
(5)

The learning rule for updating the weight vector \( W \) (containing \( W_1, W_2, b_1, \) and \( b_2 \)) is error back-propagation based on gradient descent, i.e., \( \Delta W = -\eta \cdot W_{\text{grad}} \). The error gradients with respect to \( W_1, W_2, b_1, \) and \( b_2 \) are derived as follows respectively (Abdulhussain and Gan, 2016, Zhang et al., 2015):
\[ W_1 \text{grad} = (W_1^T(O-X)+\hat{p}_j - \frac{p}{\hat{p}_j} + \frac{1-p}{1-\hat{p}_j})^T \frac{\partial^2}{\partial W_1} \]  
(6)
\[ h_{\text{grad}} = (O-X)^T / m + \lambda W_1 \]  
(7)
\[ W_2 \text{grad} = ((O-X)H^T) / m + \lambda W_2 \]  
(8)
\[ b_1 \text{grad} = (O-X)I / m \]  
(9)
where \( g'(H) = g(H) \cdot [1 - g(H)] \) is the derivative of the sigmoid logistic function, \( I = [1,1,...,1]^T \) is a one vector of size \( m \) and \( \cdot \) represents element-wise multiplication.

2.2 Deep Multilayer Perceptron (DMLP)

A deep multilayer perceptron is a supervised feedforward neural network with multiple hidden layers (Glorot and Bengio, 2010). For simplicity, Figure 2 illustrates a DMLP with 2 hidden layers only (There are usually more than 2 hidden layers).

![Figure 2: Deep multilayer perceptron (DMLP).](image)

2.3 Proposed Approach

Training deep neural networks usually needs a huge amount of training data, especially in high-dimensional input space. Otherwise, overfitting would be a serious problem due to the high complexity of the neural network model. However, in many applications the required huge amount of training data may be unavailable or the computer power available is insufficient to handle a huge amount of training data. With deep neural network training, there may also be local minimum and vanishing/exploding gradient problems without proper weight initialisation. Deep classifier structures with stacked autoencoder are investigated in this paper to overcome these problems, whose training process consists of the following three stages:

1) At the first stage, unsupervised learning is adopted to train a stacked autoencoder with random initial weights to obtain the initial weights of the feature extraction layers of the DMLP. The autoencoder consists of \( N \) input units, an encoder with two layers of \( K_1 \) and \( K_2 \) neurons in each hidden layer respectively, a symmetric decoder, and \( N \) output units. Figure 3 illustrates its structure.

2) At the second stage, error back-propagation is employed to pre-train the DMLP by fixing the weights obtained at the first stage for its feature extraction layers (\( W_1 \) and \( W_2 \)). The weights of higher hidden layers and output layer for feature classification (\( W_3, W_4, \) and \( W_5 \)) are trained with random initial weights. Figure 4 illustrates how it works.

3) At the third stage, all the weights of the DMLP obtained at the second stage are refined by error back-propagation, without random weight initialisation. Figure 5 illustrates how it works.

In our experiment, three methods are compared. The first method, M1, is SVM (Vapnik, 2013) with the output of the SAE encoder as input, the second method, M2, is the pre-trained DMLP as shown in Figure 4, and the third method, M3, is the DMLP after refined-training as shown in Figure 5. Their classification performances are evaluated on several datasets.
3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 Data Sets

Three document datasets were used in the experiments. First, a phishing email dataset (http://snap.stanford.edu/data/) has 6000 samples from two classes (3000 ham/non-spam and 3000 phishing), collected from different resources such as Cornell University and Enron Company. Second, the Musk dataset (http://archive.ics.uci.edu/ml/datasets.html) has 6598 samples from two classes (musk and non-musk). Third, a phishing technical feature dataset (http://khonji.org/phishing studies) has 4230 samples from two classes (2115 phishing and 2115 non-phishing).

The documents in these datasets were pre-processed by tokenization, removing stop words such as ‘the’, numbers and symbols, which helps to produce a bag of words (BOW) as original features (George and Joseph, 2014).

Term presence (TP) as weighting scheme was then applied to the words in the BOW to obtain numerical feature values (George and Joseph, 2014). The total numbers of features for phishing emails, Musk, and phishing technical feature datasets are 750, 166, and 47 respectively.

3.2 Experiment Procedure

Each dataset was partitioned into a training set and a testing set. The training set was further partitioned into estimation set and validation set for k-fold cross-validation to determine the optimal or appropriate network structure and hyper-parameter values ($\lambda$, $\beta$, $p$).

The proposed method was evaluated with different number of hidden layers and different number of hidden neurons during cross-validation, and each testing set was only used once to evaluate the performance of the proposed method with the network structure trained using the hyper-parameter values chosen by the k-fold cross-validation.

For a typical DMLP with 4 hidden layers, the numbers of hidden neurons in the first stage are $K_1$ and $K_2$ respectively, and the numbers of hidden neurons in the second or third stage are $K_1$, $K_2$, $K_3$, and $K_4$ respectively. For training the SAE, 8 sets of hyper-parameters ($\lambda$, $\beta$, $p$) were validated, as shown in Table 1, which are around the suggested default values.

3.3 Results

1) Classification Accuracy: Tables 2-4 show the cross-validation classification accuracies of the three methods (M1, M2, and M3) with different hyper-parameter values and different number of hidden neurons, on the three datasets respectively. Tables 5-7 show the corresponding training and testing accuracies of the three methods with the appropriate network structure trained using the hyper-parameter values chosen by the cross-validation. Figure 6 compares the three methods in terms of average training and testing accuracy. It can be seen from Figure 6 that the proposed three-stage learning algorithm for training deep classifier structures with SAE, i.e., the M3 method, achieved the highest accuracy, which have been proved to be statistically significantly better than other methods evaluated in the
From Figure 6 it can be seen that the proposed method (M3) has much smaller difference between testing accuracy and training accuracy than methods M1 and M2, which can be regarded as evidence of less serious overfitting in the proposed method. It can be concluded that DMLP with effective weight initialisation can achieve significantly better performance than the standard MLP, and it is evident that the deep classifier structures with stacked autoencoder can reduce overfitting.

Figure 6: Comparison of the three methods in terms of average training and testing accuracy.

2) Statistical Significance Test: In order to assess whether the performance differences among the methods are statistically significant, we applied T-test, a parametric statistical hypothesis test, and the Wilcoxon’s rank-sum test, a non-parametric method, to determine whether two sets of accuracy data are significantly different from each other. The statistical tests were conducted on three paired methods (M3 vs M1, M3 vs M2, and M2 vs M1) in terms of testing classification accuracy. Tables 8 and 9 show the p-values from these tests, which demonstrate that, in terms of classification performance, M3 significantly outperformed M1 and M2, and M2 significantly outperformed M1.

4 CONCLUSIONS

This paper investigates deep classifier structures with stacked autoencoder for higher-level feature extraction. The proposed approach can overcome possible overfitting and vanishing/exploding gradient problems in deep learning with limited training data. It is evident from the experimental results that the deep multilayer perceptron trained using the proposed three-stage learning algorithm significantly outperformed the pre-trained stacked autoencoder with support vector machine classifier. Also, it can be seen that the proposed method (M3) has much smaller difference between testing accuracy and training accuracy than methods M1 and M2, which can be regarded as evidence of less serious overfitting in the proposed method. Preliminary experimental results have demonstrated the advantages of the proposed method. Further tests on this algorithm would be applied to deep neural networks with more layers and hopefully would beef up the performance of these networks. Also, tests with other applications would be conducted in future investigations.
