Keywords: Result Prediction, Game Analysis, Sport Analytics, Soccer Match Prediction, Machine Learning.

Abstract: Sport result prediction proposes an interesting challenge considering as popular and widespread are sport games, for instance tennis and soccer. The outcome prediction is a difficult task because there are a lot of factors that can afflict the final results and most of them are related to the player human behaviour. In this paper we propose a new feature set (related to the match and to players) aimed to model a soccer match. The set is related to characteristics obtainable not only at the end of the match, but also when the match is in progress. We consider machine learning techniques to predict the results of the match and the number of goals, evaluating a dataset of real-world data obtained from the Italian Serie A league in the 2017-2018 season. Using the RandomForest algorithm we obtain a precision of 0.857 and a recall of 0.750 in won match prediction, while for the goal prediction we obtain a precision of 0.879 in the number of goal prediction less than two, and a precision of 0.8 in the number of goal prediction equal or greater to two.

1 INTRODUCTION

The Oxford dictionary defines tactic as “an action or strategy carefully planned to achieve a specific end”. In case of sport matches the specific end is to win the match. The definition of a tactic, from the coach point of view for instance, is depending on several factors (most of these are human behaviour-related), for instance: the players, in terms of physical conditions and/or harmony with teammates; the opposing team, in terms of technical and resistance skills; the tactic adopted by the coach of the opposed team; the stadium where the game is played.

For these reasons, the winning of a match is not related just to one factor (Lucey et al., 2014), but there are several aspects that contribute to this end. Considering how widespread are sports, there is an increasing interest in developing methodologies and techniques aimed to predict a match result examining a set of indicators (Dijksterhuis et al., 2009) (generally based on statistics related to previous matches).

Typically, the main weakness of the current state-of-the-art research is two-fold. The first one relates to methodologies while the second one relates to the evaluation of the proposed methods.

With regard to the methodology weakness, literature presents methods analyzing feature set available only at the end of matches, for instance the number of goal or the number of red cards received by the players. This is the reason why it is not possible to predict the result of a match in progress, and this represents a limitation because in this way the coach is not able to change the tactic for instance, between the first and the second time.

The second weakness is related to the evaluation of the proposed method. Probably for the novelty of the topic, the researchers do not have available a dataset of real-data to analyse the proposed solution and to compare its effectiveness with the other methods. This is an important issue, because currently it is not possible to compare the performances of the various methodologies proposed. This problem is discussed by Rein and colleagues (Rein and Memmert, 2016): they stated that one of the main problems in sport analytics is the lack of available and relevant data and this is becoming an obstacle in itself for the modelling of tactical decision making in team sports.

From the other side, big data researchers affirm that, with the development of advanced tracking technologies, this situation will change in a while. Indeed,
they sustain that the amount of available data related to sport analytics is becoming increasingly difficult to manage (Lohr, 2012; Silva et al., 2016): we will assist to the opposite situation, researchers will have a lot of data available and the difficult task will be the extraction of knowledge from heterogeneous sources.

Starting from these considerations, in this preliminary paper we propose a method trying to solve the first weakness. In particular, we propose to analyze real-time the game to predict match results in the context of the soccer game and it is also able to determine whether the match under analysis will be won with more or less than two goals (in order to provide a more fine-grained prediction).

In a nutshell, exploiting super-visioned machine learning algorithms, we build two models: the first one to abstract the win or loss of a match, while the second one able to model the number of goals scored by the winning team. We consider a feature set related to characteristics obtainable not only at the end of the match, but also when the match is in progress.

In the evaluation, using real-world data gathered from the Italian Serie A League from 378 different matches related to the 2017-2018 season, we obtain a precision and a recall greater than 0.8 outperforming the performance of state-of-the-art methods proposed in current literature. The paper proceeds as follows: Section 2 discusses the current literature related to soccer result prediction, Section 3 deeply describes and motivates the proposed method; Section 4 illustrates the results of the experiments and finally, conclusions are drawn in Section 5.

2 RELATED WORK

Recently, machine learning techniques have been introduced in sport analytics with the aim to predict match results or to obtain an improvement of the team performance. With regard to soccer analytics, a general issue is that most of the work has been done using datasets with a very limited number of predictors, due to the lack of public data about soccer games. For this reason, there are few studies in soccer analytics in which the data are analyzed using machine learning techniques. Among the related works in the literature, authors in (Joseph et al., 2006) present an approach to forecast results in which the Bayesian Networks provide a means for representing and predicting the results of expert knowledge in a football domain in terms of predictive accuracy. Specifically, authors obtain accuracy of 59% which outperformed other machine learning algorithms by 41.7% (MC4), 47.86% (NB) and 50.58% (KNN). In (Kumar, 2013), the author has evaluated a set of machine learning algorithms in order to classify the 3 label result variables i.e., win, draw and loss: authors observed the best performance with the multilayer perceptron algorithm with an accuracy equal to 69.474 % and a ROC area equal to 0.836. In (Liti et al., 2017) it has been considered the problem of predicting the outcome of a soccer match finished with a draw at the end of the first half using mainly the information stored during the first part of the match. The dataset considered in this study contains the results of 166 matches and, after removing the attributes containing few values different from zero, the final set of feature is composed of 27 attributes. Firstly, the authors have used a feature selection method and, then a classification task on a three label result variables - home win, away win or draw. The RBF network is the algorithm that performs better, with an accuracy equal to 45%.

In (Sathe and Satao, 2017) the authors have used multiple classification algorithms such as support vector machine, random forest and Naive Bayes. The best performing algorithm in that study is SVM, having an accuracy equal to 0.599 followed by Naive Bayes with an accuracy equal to of 0.55. Random forest is the algorithm with worst performance, with an accuracy equal to 0.50. Many studies have been performed on Premier League matches. In (Razali et al., 2017), it has been used a Bayesian networks approach. This research uses predictors as home and away team shots, home and away team shots on target, home and away corners, half time home and away team goals, and so on, to predict the match outcome of a team. In particular, the study considered the English Premier League for the seasons of 2010-2011, 2011-2012 and 2012-2013. It has been used a 10-folds cross-validation to perform the classification, and the results have an accuracy, in average, equal to 74%. In that research, the authors use predictors that give direct information on the outcome of a specific match, so variables that are strongly correlated to the predicted variable, as goals scored in the first and second half. (Baboota and Kaur, 2018) demonstrates the building of a generalized pre-
dictive model for predicting the results of the English Premier League. Firstly, the authors have used feature engineering and exploratory data analysis to create a feature set for determining the most important factors for predicting the results of a football match. Then, a highly accurate predictive system using machine learning has been created. The best model of that study uses gradient boosting, achieving a performance of 0.2156 on the ranked probability scores (RPS) metric for game weeks 6 to 38 for the English Premier League. A different feature set is considered in (Gomes et al., 2015): they obtain a lower average accuracy if compared to the method we propose (even if they consider also the draw matches).

Differently from the discussed methods, we consider types of data never explored in literature and that are not strongly correlated with the predicted variable, for instance, attributes related to the spatial disposition of the team in the field, as the team’s center of gravity or the area of the convex hull created by the disposition of the players, both in attacking and defensive stage. Another novelty of our work is the two-label classification (win or no-win) considered, since our goal is to identify the main team aspect of the match, which we can modify in order to improve the performance to win a match. This means that our work could be useful to create, in future, a notational analysis system that a coach could use to change the strategy or the organization of the team during a match, i.e., at halftime.

3 THE METHOD

In this section we present the proposed method depicted in Figure 1. It is divided in two main phases: the Model Building (i.e., Phase I in Figure 1) and the 2-step Result Prediction (i.e., Phase I in Figure 1).

The Model Building phase is related to the training aimed to build the two models to predict the match result and the goal number and it is composed by following modules: match reports: this module is able to data acquisition in raw format from completed matches using a plethora of information sources, for instance, digital newspapers, sport websites and RSS feed; feature cleaning and preprocessing: the aim of this module is to filter the raw data obtained in the previous step in order to extract the feature set for each match that will be considered in the two models. Basically, from the raw data for the matches, the output of this module is a well-formatted CSV file in which, for each examined match, the considered features appear; match model building: this module considers the feature set obtained in the previous step to build a model using the win or lose label associated to each feature vector (i.e., a match); goal model building: this module considers the feature set obtained in the previous step to build a model using the < 2 or >= 2 label associated to each feature vector (i.e., a match). The < 2 label is related to a match won with a number of goals less than 2, while the >= 2 label is associated to a match won with a number of goals equal or greater than 2.

Once obtained the two models related to the main result of the match and to the goal number, the 2-step Result Prediction phase has the responsibility to evaluate the results (in terms of win/lose and number of goals) of new matches. As a matter of fact, the features vector evaluated in the proposed method can be also used to evaluate match in progress, for instance the coach, between the first and second half, could be able to real-time predict the outcome of the match, and then think about changing the game strategy in order to win the game.

The 2-step Result Prediction phase is composed by following modules: match under analysis: the aim of this module is the same of the first module in the Model Building phase: in the real-world the developed method can be also used from coaches inserting by hand the reports related to previous match or the partial result of a match; feature cleaning and preprocessing: this module is responsible to obtain the feature set from the raw information obtained in the previous step, in addition it is also able to parse the information inserted by the coach using an interface provided by the system in order to convert the information into a feature vector to input the two models built in the Model Building phase; match predictor: this module represents the match evaluator. It takes as input the feature vector and tests it against the model built in the match model building module of the Model Building phase (this is the reason why the inputs of the match predictor module are the match model building module and the feature vector). The output of this module is a label: win whether the prediction, considering the analysed feature vector, is a win of the match under analysis or lose, whether the prediction is a lose of the match; goal predictor: this module represents the goal evaluator. The inputs of this module are the goal model building module and the feature vector. Whether the match predictor module predicts a win of the match under analysis, the goal predictor module analyses the feature vector in order to predict whether the
analysed match will be win with a number of goals less then two (in this case the feature vector will be marked with the $< 2$ label) or with a number of goals equal of greater than two (in this case the feature vector will be marked with the $\geq 2$ label).

Once depicted the high-level architecture of the proposed method, we discuss in details the feature vector we considered to build the two models. Table 1 shows the considered features. We consider from the initial dataset only 20 features i.e., the best feature set obtained using the Best-first search principal component analysis.

We designed an experiment in order to evaluate the effectiveness of the feature vector that we propose to detect the match results and the number of goal.

The evaluation consists of classification analysis aimed at assessing whether the features are able to correctly classify between won and lose matches.

In order to perform the classification task, we selected six different classification algorithms (to improve the conclusion validity): J48, SMO, RepTree, RandomForest and MLP. For details about the algorithms the reader can refer to (Wu et al., 2008).

4 EXPERIMENTAL EVALUATION

In this section we present the results of the experiment we performed to validate the effectiveness of the proposed method.

Reflecting the organization of the previous section, below we present the descriptive statistics in order to provide statistical evidence that the considered feature set are discriminating between lose and win matches; and the classification analysis aimed to build model able to predict real-world match results in terms of won and lose matches and number of goal of the winning team.

4.1 The Dataset

The dataset has been constructed from the pdf files match report provided by the Serie A league, for each match of the season 2017-2018. The dataset contains 98 attributes and 378 instances. Each instance represents a specific match in the league.

We have different types of attributes, for each team of the match, as:

- attributes that give us information about possession, in each half time;
- attributes that give us information about the spatial disposition of the player in the field - area, measured in $m^2$, or the center of gravity of the team in attacking and defensive stage;
- attributes that gives us information about the goals scored and conceded;
- other types of information about the teams participating to the specific match.

The data were obtained using a Java script developed by the authors able to retrieve the required information and to create the dataset.

4.2 Classification Analysis

We considered five metrics in order to evaluate the results of the classification: FP rate, Precision, Recall, F-Measure and ROC Area.

The precision has been computed as the proportion of the examples that truly belong to class $X$ among all those which were assigned to the class.

\[
\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}
\]

where TP is the number of true positives and FP is the number of false positives.

The recall has been computed as the proportion of the examples that truly belong to class $X$ among all those which truly belong to class $X$.

\[
\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}
\]

where FN is the number of false negatives.

The F-Measure is the harmonic mean of precision and recall.

\[
\text{F-Measure} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}
\]

The ROC Area is a measure of the discrimination ability of the classifier.

The data were obtained using a Java script developed by the authors able to retrieve the required information and to create the dataset.

</table>

The F-Measure is a measure of a test’s accuracy. This score can be interpreted as a weighted average of the precision and recall:

$$F-Measure = 2 \frac{Precision \times Recall}{Precision + Recall}$$

The Roc Area is defined as the probability that a positive instance randomly chosen is classified above a negative randomly chosen.

The classification analysis consisted of building classifiers in order to evaluate the feature vector accuracy to distinguish between win and lose matches.

For training the first classifier (the one related to the match model building module in Figure 1), we defined $T$ as a set of labeled messages $(M, l)$, where each $M$ is associated to a label $l \in \{\text{win, lose}\}$. For each $M$ we built a feature vector $F \in R_y$, where $y$ is the number of the features used in training phase ($y = 20$). The label win is associated to a won match, while the label...
lose is related to a lose match.

To train the second classifier i.e., the goal model building in Figure 1 we consider the a similar procedure like the one followed for the match model building module. In this case we defined $T$ as a set of labeled messages $(M, l)$, where each $M$ is associated to a label $l \in \{< 2, >= 2\}$ using the same feature vector considered in the previous model. The label $< 2$ is associated to a won match with a number of goal less to 2, while the label $>= 2$ is related to a match won with a number of goal equal or greater than 2.

For the learning phase, we use a k-fold cross-validation (Arlot et al., 2010); the dataset is randomly partitioned into $k$ subsets. A single subset is retained as the validation dataset in order to evaluate the obtained model, while the remaining $k-1$ subsets of the original dataset are considered as training data. We repeated the process for $k = 20$ times; each one of the $k$ subsets has been used once as the validation dataset (Nasrabadi, 2007; Shaikh et al., 2016). To obtain a single estimate, we computed the average of the $k$ results from the folds.

The procedure is repeated two times: for the the match model building and the goal model building modules.

We evaluated the effectiveness of the classification method with the following procedure:

1. build a training set $T \subset D$;
2. build a testing set $T' = D \setminus T$;
3. run the training phase on $T$;
4. apply the learned classifier to each element of $T'$.

In the flowchart depicted in Figure 1 the evaluation of the match model building is represented by the match predictor module, while the evaluation of the goal model building is represented by the goal predictor module.

Each classification was performed using 95% of the dataset as training dataset and 5% as testing dataset employing the full feature set.

As shown in Table 2, we obtain an average precision ranging from 0.735 (with the J48 algorithm) to 0.843 with the RandomForest algorithm. With regard to the recall, this metric in average is ranging from 0.684 (with the RepTree algorithm) to 0.842 (obtained with the SMO and the RandomForest algorithm).

**RQ1 response:** the obtained results show that machine learning techniques can be able to predict soccer match results. The best performances in terms of precision and recall were obtained by the RandomForest algorithm, with a precision equal to 0.857 and a recall equal to 0.750 to predict a won match.

As previously discussed, for each classification we considered 95% of the dataset as training dataset and 5% as testing dataset employing the full feature set.

In order to show the performances when the training set is increasing, Figure 2 depicts the precision and recall trend with training set percentages ranging from 90% to 95%.

![Figure 2: Bar charts related to precision and recall with different training set percentages (from 90% to 95%) using the RandomForest algorithm.](image)

When the model is built with the 90% of the training set, both the precision and the recall are equal to 0.739. The best performances are obtained when the training set is equal to 95% (obtaining a precision equal to 0.833 and a recall equal to 0.909).

We adopted this fragmentation between training and testing dataset considering the limited number of instances in the dataset (with the aim to build a more accurate model to predict match results and the goal number) (Michalski et al., 2013; Jordan and Mitchell, 2015; Carbonell et al., 1983).

Table 3 shows the results obtained in the evaluation of the goal predictor module.

The best algorithm for goal number prediction is RandomForest, with an average precision equal to 0.862 and an average recall equal to 0.868. The less performing algorithms is J48, with an average precision equal to 0.749 and an average recall equal to 0.699. RandomForest algorithm outperforms the other algorithms since it considers a multitude of trees differently from the other considered classification approaches.

**RQ2 response:** the goal prediction analysis demonstrate that machine learning techniques exhibit the ability to predict the number of goals scored by the winning team. In detail, the RandomForest algorithm obtained a precision equal to 0.879 in the number of goal prediction less than two, and a precision equal to 0.8 in the number of goal prediction equal or greater to two.

5 CONCLUSIONS AND FUTURE WORK

Considering the popularity of soccer, in last year sport analytics related to soccer is a research topic with a growing interest.

In this paper we design a methodology aimed to predict the result of a soccer match and the number of goals scored by the winning team. The key point of the proposed method is the use of features (related to the single player but also to the group of players) that are obtainable before the end of the match. In this case the coach is able to real-time predict the result of a match before the end of the match under analysis. In this case he can change the tactic. The proposed method exploits machine learning techniques and models built using J48, SMO, RepTree, RandomForest and MultilayerPerceptron classification algo-
rithms have been evaluated.

We obtained a precision equal to 0.857 and a recall equal to 0.750 in the won match prediction, while an average precision equal to 0.862 is obtained in the number of goal prediction.

As future work, we plan to investigate whether the proposed method is applicable to other sports like, for instance, basketball or tennis. Furthermore, with the aim to increase the obtained performances, we plan to evaluate whether emerging deep learning algorithms can be useful in order to detect match results with better performances. Moreover, we plan to apply formal methods (De Francesco et al., 2016; Santone et al., 2013; Avvenuti et al., 2012) which have been already been demonstrated to be effective in other domains, like for example in biology (Ruvo et al., 2015).
