Keywords: Satellite, Ground Station, Earth Remote Sensing, Multi-agent Technology, Multi-agent System, Target Planning, Precision Agriculture.

Abstract: The paper considers the task of constructing a schedule for target application of space remote sensing systems for solving problems of precision farming. It also proposes a method of their solution using multi-agent technology. Presented models and algorithms allow for solving the urgent problem of network interaction between heterogeneous spacecraft group devices for implementation of enlarged and detailed territory surveys, as well as adaptive planning of user requests for shooting. Results of experiments demonstrate higher efficiency of the developed algorithms on large-scale problems in comparison with methods of traditional centralized planning.

1 INTRODUCTION

Modern agriculture is increasingly shifting towards an intensive type of development, one of the most promising tools of which is precision farming. Precision farming is a system of agricultural production, which uses information technology, extracting data from many different sources, and ensuring adoption of optimal decisions in management of an agricultural enterprise. The basis of the system is the use of accurate maps of fields with all their characteristics. Taking into account a large number of factors makes it possible to get a detailed map of individual sections of the field, assess their condition and, if necessary, promptly adjust the production process. To speed up the process of collecting relevant data on the current state of farmland, it is helpful to use space systems of Earth remote sensing (Liaghat, 2010) which is an up-and-coming trend now.

Analysis of shooting results helps quickly and accurately assess the area of agricultural land, the state of crops: impurity, sparseness, death after drought, flooding or other damaging factors, and trace stages of their phenological development. All this information helps respond quickly to changes in the state of crops, and make timely decisions, which leads to an increase in efficiency of farming in general (McCabe, et al., 2016).

As part of implementation of this methodology, the Samara National Research University is designing a space system consisting of a group of AIST satellites (two of them are in orbit, and five are planned to be launched soon) with multispectral equipment for receiving index characteristics of agricultural fields and ground stations (Kirilin, 2017). Accordingly, there appears the task of planning target application of Earth remote sensing space systems for solving precision farming tasks.

The first chapter of this paper discusses the need to use data from Earth remote sensing survey for precision farming. The second chapter describes this problem in more detail and proposes the method for its solution using multi-agent technology. The third chapter provides statement of the planning problem. The fourth chapter describes the data model used in the planning process. The fifth chapter thoroughly considers the planning stages. The sixth chapter proves effectiveness of the used technologies and algorithms, based on results of experiments. Conclusions suggest further stages for development of the system.
2 PROBLEM DESCRIPTION AND PROPOSED APPROACH TO ITS SOLUTION

The task of constructing a schedule for target application of space systems for conducting operational object sounding is as follows: based on applications from users for monitoring agricultural fields during a specified period with the given frequency, and taking into account restrictions on image characteristics, the system forms a comprehensive plan for execution of applications, satisfying the given requirements (Darnopykh, 2004).

Complexity of this task lies in heterogeneity of technical characteristics and principles of organization of onboard equipment of the satellite, as well as in large dimensions: dozens of satellites and ground stations are used, and a large number of point-type observation objects is specified. The period for performing shooting or data transmission operations is limited by a non-permanent visual contact between satellites and observation objects, as well as by the radio contact between satellites and ground stations.

Limitations on technical characteristics of onboard equipment and external restrictions (cloudiness, illumination, etc.) are constraining performance of operations. The presence of several devices increases the number of potentially possible surveys of ground objects, which leads to multivariance of shooting plans. It is necessary to ensure prompt decision-making without recalculating the entire schedule when a new event appears in multi-criteria environment.

Traditional centralized planning is based on mathematical methods: branch and bound method, nonlinear programming, mathematical and dynamic programming, discrete optimization, constraint programming, genetic algorithms.

Disadvantages of centralized planning are the following: determinacy and complexity of taking into account rapidly changing conditions, lack of reliable information about the current situation, loss of schedule adequacy over time. It is possible to overcome these disadvantages through the use of distributed approach, in particular, multi-agent approach to planning.

The Distributed Constraint Optimization Problem (DCOP) methodology implements the use of agents in optimization problems with constraints in distributed systems (Meisels, 2008). The algorithms take into account the network structure of the problem. The general principle of such algorithms is decentralization in decision-making, dynamic nature of emerging decisions and gradual striving for equilibrium in conditions when in the presence of external influences the multi-agent system finds a new equilibrium position. However, a disadvantage of distributed algorithms is exponential growth either of the number of messages exchanged by agents or of their volume (Yokoo, 2001, Petchu, 2009). To reduce growth various heuristics are used.

(Pinto, et al., 2018) discusses a method for optimizing planning of interaction in a group of satellites and ground stations, taking into account priorities and operational constraints. In (Wörle, et al., 2015), a system of incremental mission planning for spacecrafts is described, in which operations are rescheduled in the shortest possible time to meet new restrictions and rules.

For practical solution of the planning problem for survey schedule, it is proposed to divide the planning process into two stages:

1. Conflict-free planning, the goal of which is to obtain initial acceptable schedule.
2. Proactive planning that tries to improve the resulting schedule.

When planning, it is necessary to dynamically adjust the schedule of target application of the space system as new applications are received, application parameters or composition of the space system change, or unpredictable events, related to meteorological conditions or equipment failures, happen.

Thus, the planning system for target application of the Earth remote sensing satellites can be attributed to complex adaptive systems, for efficient management of which the principle of adaptive restructuring of decisions and action plans for real-time events is proposed (Rzevski, 2014).

For the second planning stage, a multi-agent approach has been chosen, since it has proven practical effectiveness in tasks requiring operational solutions (Wooldridge, 2009, Shoham, 2009, Skobelev, et al., 2016).

As a result of agent interaction, the plan obtained at the stage of conflict-free planning is adaptively adjusted by resolving conflicts and re-planning of tasks in order to achieve the best option for their possible placement compared to the current one, in order to improve the quality of the whole schedule (Skobelev, et al., 2016).

3 DESCRIPTION OF THE PLANNING PROBLEM

To build a schedule for target application of a swarm of satellites, a simplified mathematical model of the ERS space system is used.
The model is defined by five sets \(S, G, P, C, F\):

- \(S = \{s_i\}, i = 1, L\) is the satellite set, in which each satellite \(s_i\) is characterized by orbital elements and characteristics of onboard equipment;
- \(G = G_K \cup G_R\) is the set of ground stations, where \(G_K = \{g_k\}, k = 1, K\) is the set of transmitting stations, and \(G_R = \{g_r\}, r = 1, R\) is the set of receiving stations. Each station \(g_k\) and \(g_r\) is characterized by its location, speed of receiving and transmitting data, divergence angle, as well as the possibility of using it to send a shooting program and/or receive images;
- \(P = \{p_j\}, j = 1, M\) is a set of observation objects, in which each object \(p_j\) represents an application for survey and is a point-type object described by its location;
- \(C\) is a set of restrictions, such as the time interval \([t_j^{\text{start}}, t_j^{\text{end}}]\), in which it is necessary to perform shooting of the object \(p_j\), shooting conditions (minimum angle of Sun elevation), requirements for characteristics of the used imaging equipment and spatial resolution (roll and pitch angle of the satellite during shooting);
- \(F\) is the objective function.

It is required to create the shooting schedule for the observation object by a group of satellites, compiled in accordance with the criterion of minimizing the interval between the possible start of shooting \(t_j^{\text{start}}\) and the end of transmitting the shooting results to the ground station. The criterion is given by the objective function \(F\):

\[
F = \frac{1}{M} \sum_{j=1}^{M} F_j \rightarrow \min
\]

\[
F_j = \frac{t_j^{\text{drop}} - t_j^{\text{start}}}{t_j^{\text{end}} - t_j^{\text{start}}}
\]

where: \(t_j^{\text{drop}}\) is the time of receiving the image of the \(j\)-th observation area by the ground station.

The resulting schedule must meet the following restrictions:

1. Visibility between the satellite \(s_i\) and the observation object \(p_j\) during shooting \(t_j^{\text{shoot}} = [t_j^{\text{shootStart}}, t_j^{\text{shootEnd}}]\);
2. Visibility between the satellite \(s_i\) and the transmitting ground station \(g_k\) during transmitting the shooting program \(t_k^{\text{prog}} = [t_k^{\text{progStart}}, t_k^{\text{progEnd}}]\);
3. Visibility between the satellite \(s_i\) and the receiving ground station \(g_r\) during transmitting the shooting results \(t_{ir}^{\text{drop}} = [t_{ir}^{\text{dropStart}}, t_{ir}^{\text{dropEnd}}]\);
4. Availability of free space in the onboard storage device of the satellite;
5. Consistency in the sequence of transmitting the shooting program, the shooting itself, and transmission and reception of the shooting results;
6. Satellites and ground stations can simultaneously perform no more than one operation.

### 4 DESCRIPTION OF THE PLANNING PROCESS DATA MODEL

The developed system uses an information data model. Its simplified structure is shown in Fig. 1.

The Task class is a task that needs to be scheduled. This class has attributes that define the actual timeframe for planning \((\text{startTime}, \text{endTime})\). Each task must contain one or more operations (objects of the Requirement class). Relations within a pair of operations are defined through objects of the RequirementRules class. Requirement must specify the type of property that the resource must possess in order to perform the operation.

The Resource class describes a resource whose usage time needs to be scheduled. Each object of the Resource class can be associated with one or more objects of the Capability class, specifying the capabilities that this resource can provide.

The Evaluation class is a possible placement of one task operation. It shows duration of use of the resource capability (the Capability class object) for the operation specified by a specific time interval \((\text{startTime}, \text{endTime})\) within the selected allocation slot \((\text{startTime}, \text{endTime})\). The CompoundEvaluation class represents a variant of possible placement of a task with all its operations. This class contains a list of objects of the Evaluation class corresponding to each operation within the task.

The Assignment class represents the current placement of operations for the scheduled task. The PlacementConflict class describes placement conflicts for operations that occurred during scheduling. The information data model is the basis of ontology of the planning system, which can describe the model of any situation with the help of concepts and relations between them. An introduction to the ontology of description of action scenarios is also possible (Skobelev, 2012).
5 ADAPTIVE SPACE SURVEY SCHEDULING

There are two stages of planning a shooting schedule for an observation object.

5.1 Stage of Conflict-free Planning

First, conflict-free planning is performed. Its purpose is to quickly obtain an initial acceptable schedule with any level of quality. The solution received at this stage can show the main bottlenecks of the schedule and becomes a reference point for further improvements.

Initially, all tasks for shooting Task = \{task_j\}, j = 1, M, where M is the number of observation objects, are placed in the queue. After that, for each task_j a search is performed for no more than N options for possible placement according to the AI Algorithm 1.

As a result of the search, a set of options is received for possible placement of the task_j – C = \{c^w_j\}, w = 1, W, where W is the number of possible placement options found. All variants c^w_j are sorted in descending order of the value of the objective function F_j (2). After that, an attempt is made to schedule task_j in accordance with the best placement option from the point of view of the objective function, according to the Algorithm 2.

After this, the task is placed in the queue again. The conflict-free stage is completed if, during the next planning iteration, there are no new options for possible placement for any tasks. After that, the stage of proactive planning begins.
Algorithm 2: Placement Algorithm.

**Input:** task\(_j\), C – set of placement options, SA – set of assignments representing the current schedule

**Output:** Set of assignments for task\(_j\)

1: \textbf{for} \(\forall c^w_j \in C\) \textbf{do}
2: \quad In case of violation of the limitation for simultaneous performance of operations of satellites and ground stations, conflicts occur:
3: \quad \text{conflicts} = \text{findConflicts}( c^w_j, \text{SA} )
4: \quad \textbf{if} \ \text{conflicts} \ \text{is empty} \ \textbf{then}
5: \quad \quad \text{assignments} = \text{createAssignments}( c^w_j )
6: \quad \quad \text{markAsPlanned}( \text{assignments}, \text{SA} )
7: \quad \quad \text{return} \ \text{assignments}
8: \quad \textbf{else}
9: \quad \quad \text{Resolve conflicts by forming new options of possible placement after removing conflict intervals from the task\(_j\) execution interval } [t^\text{\text{start}}_j, t^\text{\text{end}}_j];
10: \quad \quad \text{options} = \text{removeConflicts}( \text{task}_j, \text{conflicts} )
11: \quad \quad \text{The newly received placement options for possible placement are added to the set } C:
12: \quad \quad \text{addOptions}( \text{options}, \text{C} )
13: \quad \textbf{end if}
14: \textbf{end for}

5.2 Stage of Proactive Planning

The following list of agent classes is proposed to improve the schedule obtained during the conflict-free planning stage:

1. **RootTaskActor** – the agent exists in a single copy, and is responsible for starting and stopping proactive planning and managing creation of task agents. Functions:
   - creation of task agents after the event of the end of the conflict-free planning stage;
   - creating and deleting task agents for arising events;
   - creating task agents to which the message has been sent, but they have not yet been created;
   - tracking the number of task agents to determine the condition for stopping the proactivity stage.

2. **TaskActor** – the agent is responsible for making permutations in the schedule. It has satisfaction function (SF) (Mayorov, 2015), which allows it to determine evaluation of the current satisfaction of its demands:

\[
SF_j(c^w_j) = F_j(c^w_j), \quad (3)
\]

\[
SF = \frac{1}{M} \sum_{j=1}^{M} SF_j(c^w_j), \quad (4)
\]

where \(c^w_j\) is the current option of possible placement of the task to shoot the observation object,

\(SF_j\) is the agent satisfaction function,

\(SF\) is the system satisfaction function.

It can also change its position at the request of another task agent. In the absence of vacant possible placement options, it can create nested proactivity. To resolve conflicts, it creates the **ProactiveBroadcastWorker** agent.

3. **ProactiveBroadcastWorker** – the agent is responsible for polling conflict operations in order to move them or remove them from the schedule. Permutations of conflict operations are accompanied by a change in the values of their satisfaction functions. These values are summed up and on the basis of the result obtained, it is decided whether it is necessary to apply this permutation.

At the stage of proactive planning, task agents try to improve their objective functions by asking conflicting tasks to find other intervals for placement by shifting the time or switching to another resource (satellite or ground station). Building the chain of changes begins from the most dissatisfied agents with the lowest objective functions. The system organizes a special "working group" of agents (TaskActor), which are affected by changes (permutations and shifts in the schedule) (see Algorithm 3). Effectiveness of each permutation can be evaluated by changing satisfaction functions of the agents participating in it. The resulting version of the schedule change can be accepted or rejected depending on the effect on the system satisfaction function: only those changes are approved that do not increase the system satisfaction function (4). The function increment (4) is calculated by the following formula:

\[
\Delta SF = \frac{1}{M} \sum_{j}^{M} SF_j(c^w_j) - SF_j(c^w_j) \rightarrow \min, \quad (5)
\]

where \(c^w_j\) is the current version of possible placement,

\(\tilde{c}_j^w\) is the new version of possible placement.

When constructing chains of permutations, the following conflict situations are considered:

1. Planning a survey of the observation area by displacing previously scheduled surveys or data transmission sessions from the satellite schedule;
2. Approximation of the time of transmitting the image to the ground station by displacing previously scheduled surveys or data transmission sessions from
Algorithm 3: Proactive Planning.

Input: task_j, C – set of placement options, depth of recursion, depth_{max} – maximal recursion depth, SA – set of assignments presenting the current schedule, P – set of permutations

Output: Improved schedule

1: if depth = 0 then
2: The task agent views available options for possible placement with values of objective functions which are lower than those of the current option: options = filterByValue( C )
3: else if depth < depth_{max} then
4: The task agent only looks at placement options that do not conflict with the current permutation set:
   options = filterByPermutations( C, P )
5: else
6: The task agent only looks at conflict-free placement options that do not conflict with the current permutation set:
   options = filterByPermutations( C, P )
   options = filterByConflicts( options )
7: end if
8: for \( \forall c^w_j \in \text{options} \) do
9: Add placement option to set of permutations: addPermutations( c^w_j, P )
10: if \( c^w_j \) has conflicts then
11: Add permutations for removing conflict operations:
   addPermutations(conflicts, P)
12: for \( \forall x \in \text{conflicts} \) do
13: For each task x, corresponding to conflict x, recursive call of proactive planning is carried out:
   ProactivePlanning(task_x, C, depth + 1, depth_{max})
14: end for
15: end if
16: if depth=0 and summary change of objective function due to the received set of permutations is less than zero, then
17: Permutations are applied to the current schedule: applyPermutaitons( P, SA )
18: break;
19: end if
20: if summary change of objective function due to the received set of permutations is more than zero, then
21: Remove own and subsidiary permutations from the list:
   removePermutations(task_j, P)
22: end if
23: end for

3. Displacement of previously scheduled data transmission sessions from the ground station schedule;
4. Freeing the satellite memory device from other images in case of insufficient space in the onboard memory device.

A task that remains unplanned is placed in the task queue awaiting scheduling. Another attempt to plan these tasks will be made in case of adding new resources or changing the schedule of existing ones. The protocol of agent interaction at the stage of proactivity is shown in Fig. 2.

The iterative plan improvement continues until all task agents are stopped, which would mean reaching a consensus in negotiations and the possibility of issuing the final solution. This state can be violated when receiving events related to addition, deletion or change of parameters of satellites, ground stations or observation objects. In this case, the schedule is reduced to an acceptable form, and then improved according to the mechanism described above.

Figure 2: Agent negotiation protocol at the proactive planning stage.

### 6 CONDUCTING EXPERIMENTAL RESEARCH

#### 6.1 Studying Efficiency of Proactive Planning Algorithm

For system approbation, a model was developed containing four satellites within a satellite group and two ground stations within the network of ground
stations. 700 new tasks were added in the form of applications for shooting observation objects and transmitting the obtained images by a satellite to the ground station. The planning period was 5 days. Fig. 3 shows the change in the system objective function during construction of the schedule. Up to the 90th second, conflict-free planning took place.

As a result of conflict-free planning, 521 tasks were planned. As a result of proactive planning, the schedule was improved, the objective function value decreased by 0.11, and another 78 applications were planned, which is 15% of the number of applications planned at the conflict-free planning stage.

6.2 Studying the Ability of the System to Adapt the Schedule

The experiment evaluated ability of the system to adapt the schedule when group composition is changed. It considered the time taken to restore the schedule damaged by removal of one of the satellites. Satellite 4 was removed from the schedule obtained during the previous experiment. Removal occurred at the 120th second and this event led to an increase in the objective function value to 0.36 ($\Delta F = 0.21$). However, during the next 80 seconds, the planning system was able to parry the event and restructure the schedule, lowering the value of the system objective function to 0.18 ($\Delta F = -0.18$) (Fig. 3).

![Figure 3: Change in the objective function after failure of one of the satellites.](image-url)

6.3 Comparison with Genetic Algorithm and Branch and Bound Method

Table 1 shows the operating time of algorithms for a system consisting of two satellites and two ground stations, the number of observation objects (OO) varies from two to twelve. It is worth mentioning that in the experimental data set there is a small number of visibilities and a large number of conflicts on possibilities of shooting and transmission, which makes the search for the optimal solution even more complicated.

Based on the data in the table, scheduling with the help of genetic (GA) and multi-agent (MA) algorithms took much less time compared to the branch and bound method (BBM). However, as it is shown in Figure 4 on the graphs of objective function values, as a result of GA and MA, a less optimal schedule is obtained.

Thus, BBM is slower than GA and MA, but it guarantees optimality of the solution found. At the same time, it cannot be used for solving large-scale problems.

6.4 Comparison with Genetic Algorithm on Large-scale Problems

For GA and MA, a series of experiments were conducted in which the number of OOs varied from 25 to 400, for a system of five satellites and five GSs. According to results of the measurements made (Fig. 5), MA runs faster on tasks of higher dimensionality.

653
This is due to the fact that the time and quality of work of GA depends on the population size. In this case, both algorithms show similar results on the quality of the schedule.

The second factor that can negatively affect the operating time of GA is the increased number of conflicts during crossover and mutation operations. As a result, the objective function value of descendants is less often better than that of ancestors. This leads to a slowdown in the growth rate of objective function of the best individual in the population.

![Figure 5: Values of operating time in the experiment.](image)

7 CONCLUSIONS

The authors proposed a method for solving the problem of scheduling space imagery for precision agriculture by dividing the planning process into two stages: conflict-free planning and proactive planning based on multi-agent technology, which makes it possible to improve the resulting schedule.

Results of experiments demonstrate higher efficiency of the developed algorithms for large-scale problems in comparison with methods of traditional centralized planning.

Further research will focus on developing the ontology of the planning system, as well as improving the proactive planning algorithm by introducing resource agents. This will help add new variants of objective function for planning: uniform resource loading; minimizing the amount of resources; minimizing the cost of service execution with the ability to set the cost of resource use.
