Detecting Multi-Relationship Links in Sparse Datasets

Dongyun Nie and Mark Roantree

Insight Centre for Data Analytics, School of Computing, Dublin City University, Ireland

Keywords: Record Linkage, Relationships, Customer Knowledge.

Abstract: Application areas such as healthcare and insurance see many patients or clients with their lifetime record spread across the databases of different providers. Record linkage is the task where algorithms are used to identify the same individual contained in different datasets. In cases where unique identifiers are found, linking those records is a trivial task. However, there are very high numbers of individuals who cannot be matched as common identifiers do not exist across datasets and their identifying information is not exact or often, quite different (e.g. a change of address). In this research, we provide a new approach to record linkage which also includes the ability to detect relationships between customers (e.g. family). A validation is presented which highlights the best parameter and configuration settings for the types of relationship links that are required.

1 INTRODUCTION

Customer Relationship Management (CRM) allows companies to manage their interactions with current and potential customers. CRM combines people, processes and technology to try to understand a customer’s needs and behaviour. Getting to know each customer using data mining techniques and by adopting a customer-centric business strategy helps the organization to be proactive, offering more products and services for improved customer retention and loyalty over longer periods of time (Chen and Popovich, 2003). By using data analysis on customer history, the goal is to improve business relationships with customers, specifically focusing on customer retention and ultimately improving sales growth. A metric known as Customer Lifetime Value (CLV) can be regarded as a sub-topic of CRM which focuses on predicting the net profit that can accrue from the future relationship with a customer (Di Benedetto and Kim, 2016).

Tasks for data integration include data preparation (Pyle, 1999), knowledge fusion (Dong et al., 2014), in addition to matching the data (Bhattacharya and Getoor, 2007; Cohen et al., 2003; Rahm, 2016; Yujian and Bo, 2007; Roantree and Liu, 2014; Etienne et al., 2016; Ferguson et al., 2018) and managing streaming integration (Roantree et al., 2008). Knowledge fusion is an information integration process which merges information from repositories to construct knowledge bases. Traditionally, the knowledge base is built using existing repositories of structured knowledge. Record linkage is a specific problem within integration which has a unique computation problem. Matching all records in a pairwise fashion requires 499,500 comparisons for just 1,000 records and 4,999,950,000 comparisons for 100,000 records. This presents a significant challenge as the size of the dataset increases. Early attempts to address this problem (Baxter et al., 2003) included blocking where the matching space could be significantly reduced by splitting data into a large number of segments. By introducing blocking predicates (Bilenko et al., 2006), this technique was improved to exploit domain semantics for improved segmentation. However, most of these efforts used synthetic datasets e.g. (Mamun et al., 2016) or healthcare records e.g. (Bilenko et al., 2006). While trying to use these techniques in a very specific domain - insurance datasets - we encountered issues with a higher number of lost matches. Furthermore, we had a specific task of matching clients with family members, an approach not discussed in current related research.

1.1 Contribution

The construction of a unified record for all customers requires a fuzzy matching strategy, usually relying on the construction of a similarity matrix across all customers. However, this has two major challenges: the construction and evolution costs of a similarity ma-
trix are prohibitive and initial experiments showed that a single similarity value across many attributes had poor results in terms of matching accuracy. In this work, we present a customer matching approach which uses a modified form of Agglomerative Hierarchical Clustering (AHC) that incorporates a method for detecting overlapping segments. This hybrid approach of data mining, together with a companion ruleset to detect and link components of the same customer record, clients with family members; and clients with co-habits who have also bought policies, allows relatively fast matching while achieving high levels of accuracy. An evaluation is provided to illustrate the levels of matching that were achieved and a human assisted validation process. A longer version of this paper can be found at (Nie and Roantree, 2019).

**Paper Structure.** The remainder of this paper is structured as follows: in §2, we present a review of related research in this area; in §3, we present an overview of the system and the methodology that we used to integrate data for constructing unified client records; in §4, we introduce our segmentation method. in §5, we specify the detail of matching using modified Agglomerative Hierarchical Clustering; in §6 we present our experiments and an evaluation in terms of high level user group queries; and finally, §7 contains our conclusions.

## 2 RELATED RESEARCH

To integrate large amounts of source data, the authors in (Rahm, 2016) developed an approach to integrate schemas, ontologies and entities. Their purpose was to provide an approach that could match large numbers of data sources not only for pairwise matching but also for holistic data integration through many data sources. For a complex schema integration, they first used an intermediate result to merge schemas until all source schemas have been integrated. For entity integration, they first clustered data by semantic type and class, where only entities in one cluster were compared with each other. However, when clustering very large datasets, the time consumption increases rapidly. This is a well known problem and, in our work, we have the same issue. Their approach cannot be copied in our research as they use Linked Open Data while insurance data does not have the same properties as Linked Data. Furthermore, our unified record must create a relationship graph (connected families and co-habits) between every customer record. Thus, if we adopt their approach, a further layer of processing is still required.

The authors in (McCallum et al., 2000) present similar research to ours where they employ two steps to match references. Firstly, they used a method called Canopies, which offered a quick and dirty text distance matrix to find the relevant data within a threshold and put them in subsets. The fast distance matrix is to calculate the distance using an inverted index, which calculates the number of common words in a pairwise reference. A threshold will be applied to determine subsets and, similar to our approach, subsets may overlap. They then use greedy agglomerative clustering to identify pairs of items inside Canopies. While there are similarities in our two approaches, essentially they are limiting their approach to matching author names to detect the same author. Our matching is multi-dimensional, with similarity matrices across 9 attributes, and we are seeking to detect 3 forms of relationships, and not simply the author-author relationship in this work.

Many researchers like (Huang, 1998; Larsen and Aone, 1999; Hotho et al., 2003; Sedding and Kazakov, 2004; Bilenko et al., 2006; Mamun et al., 2016; Ferguson et al., 2018) all provide methods for managing text values while clustering where the common method is to use blocking techniques with n-grams or k-mer and convert strings to vectors. One applies tf (term frequency) or tf-idf (term frequency by inverse document frequency) to weight the vector, so that clustering vectors calculate the distance using similarities. All of these experiments use either semantic datasets, reference datasets or text documents. In attempting to use these approaches, we are facing many mismatches as records for the same customer (or for family members) were placed in separate segments. However, string matching approaches as discussed in this literature are often inadequate where we are trying to determine if two entities (customers) are the same. The nature of string matching will give many false positives (for actual customers) and can miss - or rank much lower - two entities which may refer to the same customer.

## 3 MATCHING METHODOLOGY

Our methodology comprises 5 steps: pre-processing; segmenting the recordset; application of the matching algorithm; using a ruleset to improve matching results; and validation.

**Step 1: Pre-processing.** This step involves cleaning data before matching can commence. Firstly, all characters are converted to lowercase to eliminate the dissimilarity due to case sensitivity. Secondly, all non-alpha-numeric characters are removed. Finally, the 4-attribute address is concatenated but the most abstract
level of granularity (normally country) is removed.

**Step 2: Dataset Segmentation.** Our validation dataset contains 194,396 records and will require approximately 20 billion comparison operations for a single evaluation using a single attribute. For this reason, the first task is to segment the recordset with the goal of minimizing the possibility of a customer having records in separate segments, as those records will never be matched. The most commonly used segmentation methods are clustering with vectoring attributes (Baxter et al., 2003). However, in almost all of these research projects, they seek only to match the same *person* which is referred to as *Client-Client* matching using our approach. However, a separate goal is to link family members and non-family member co Habitants. Details are provided in §4.

**Step 3: Clustering Client Records.** We adopt a clustering approach based on Agglomerative Hierarchical Clustering (AHC) (Day and Edelsbrunner, 1984), where a similarity matrix is computed to represent the distance between each pair of records. We do not construct a single 2-dimensional matrix but instead compute a multidimensional matrix which enables us to examine distance measures across different variables. We chose this method due to poor results obtained when using a single aggregated distance measure across all variables. There are nine dimensions in our current similarity matrix as presented in Table 1, with each dimension (matrix) given a specific label comprising *SM*, and the name of the attribute. This reference to similarity dimensions (or matrices) is also used in the rules presented in §5. The *SM_BirthDate* dimension captures the distance between dates of birth; *SM_FirstName* and *SM_LastName* for the first and last names; *SM_Address* for the distance between address strings; *SM_Email*, *SM_Mobile*, *SM_HomePhone*, *SM_WorkPhone* and *SM_Fax* for the distance between each type of contact details.

</tbody>
</table>

**Step 4: Application of Rules.** While using a multidimensional similarity matrix allows for a more fine grained comparison of distance between client records, the application of all dimensions was not suited in all matching requirements. Furthermore, we required a facility to apply different thresholds across the dimensions. There are three types of matches required in our research: client matches (records for the same client); family matches (family members for a client); and domiciled (where non-family members reside at the same address). The support dimensions for each type of match with the label: Required (Y); Not Required (N); Optional (O) shown in Table 1.

To count the number of matches for family, it is necessary to exclude same-client matches and for the domiciled matches it is necessary to exclude family and same-client matches.

## 4 DATASET SEGMENTATION

Similar to other approaches, we seek to match two different records for the same client. However, we must also identify family members as a parent or spouse may buy a policy for their child or partner. It is not unusual for this type of relationship to have a higher matching score than for two records are the same client. Our approach also matches (non-family member) co-habitants. In this section, we present a hybrid segmentation method which seeks to reduce the matching (search) space between records.

While attempting record linkage for a large dataset, most approaches (e.g. (Etienne et al., 2016; Ferguson et al., 2018)) to perform segmentation adopt a clustering approach that employs blocking and a form of vectorization for fast processing of the large pairwise matching required in their similarity matrix. Blocking involves the selection of a block (always small e.g. 3 chars) of consecutive characters which are used for distance matching. This can be illustrated using Table 2 which contains 5 sample records after our pre-processing step. Customer records 1 and 5 refer to the same client where a mistake was made for dimension *BirthDate*. Customer records 1, 2 and 3 are family members with shared *Contact* (Dimension 5 to 9) information. Additionally, customer 4 lives with customer 5. Figure 1 allocates the sample records from Table 2 into their respective segments (one of 18 possible segments) based on the block that represents each segment. Our *overlapping* approach is different to other approaches: if that block is found in any attribute in the same record, it is placed into that segment. Thus, a record can appear in more than one segment, e.g. record #1 is placed into segments 1, 4, 8, 12, 13, 14 and 15.

This was necessary as, in early tests using the DBSCAN clustering method (Han et al., 2011), up to 30% of records for the same clients were in separate

5 RULE ASSISTED MATCHING

In constructing similarity matrices, we treat all attributes as strings and generate Levenshtein distance (Kruskal, 1983) measures. The end goal is a unified customer record containing three different relationships: records for the same client; records of family members; and those of cohabitants (domicile). We begin with construct the multi-dimensional similarity matrix with a similarity measure for each attribute. Rules are applied to set distance thresholds according to each relationship. Finally, we merge the related records into unified client records.

While null values are very common in a real-world customer dataset, it makes it even more difficult to deal with the problem of evaluating similarity between two customers. If a value of null is present for the same attribute in both records, the distance will be 0, means that providing no information will result in an exact match. Thus, null values distort our methodology and therefore, we punish null values. We have 3 categories of rules, Client, Family and Domicile, which are applied according to the type of match required. The size of the similarity matrices depend on the length of the block and the number of the attributes. We describe the different configurations of blocking and attributes in §6.

5.1 Client Rule

Definition 1. Client-Client Rule

[DOB Check] and 
([Full_Name_Check]* or ) and 
[Contact_Detail_Check]

In Definition 1, we introduce the Client-Client Rule as a rule which must have 3 separate clauses, each separated by a logical and operator. All conditions must evaluate to true if records are to be clustered (matched). The condition ([Full_Name_Check]* or ) will contain one or more than one clause of Full_Name_Check separated by a logical or operator.

Definition 2. DOB Check

SM_BirthDate[i,j] ≤ TDOB
In Definition 2, the \textit{DOB\_Check} clause is specified as a Boolean statement. In this case, the similarity for records \(i\) and \(j\) are tested using the \textit{SM\_BirthDate} similarity matrix against a specified threshold value \(T_{DOB}\).

\textbf{Definition 3.} \textit{Full\_Name\_Check}

\begin{itemize}
  \item \texttt{[FirstName\_Check]}
  \item \texttt{[LastName\_Check]}
\end{itemize}

In Definition 3, the \textit{Full\_Name\_Check} clause is a Boolean statement with two conditions \texttt{FirstName\_Check} and \texttt{LastName\_Check} separated by a logical \texttt{or} operator.

\textbf{Definition 4.} \textit{FirstName\_Check}

\[ SM\_FirstName[i, j] \leq T_{FName} \]

In Definition 4, the \textit{FirstName\_Check} clause is specified as a Boolean statement. In this case, the similarity for records \(i\) and \(j\) are tested using the \textit{SM\_FirstName} similarity matrix against a specified threshold value \(T_{FName}\).

\textbf{Definition 5.} \textit{LastName\_Check}

\[ SM\_LastName[i, j] \leq T_{LName} \]

In Definition 5, the \textit{LastName\_Check} clause is specified as a Boolean statement. In this case, the similarity for records \(i\) and \(j\) are tested using the \textit{SM\_LastName} similarity matrix against a specified threshold value \(T_{LName}\).

There are two similarity matrices \textit{SM\_FirstName} and \textit{SM\_LastName} along with their specified threshold values \(T_{FName}\) and \(T_{LName}\) in \textit{Full\_Name\_Check} clauses need to be tested together. The threshold applied to this clause may present in multiple ways such that the sum of \(T_{FName}\) and \(T_{LName}\) is equal to the given number.

\textbf{Definition 6.} \textit{Contact\_Details\_Check}

\begin{itemize}
  \item \texttt{[Address\_Check]}
  \item \texttt{[Contact\_Check]}
\end{itemize}

In Definition 6, the \textit{Contact\_Details\_Check} clause is a Boolean statement with two clauses \texttt{Address\_Check} and \texttt{Contact\_Check} separated by a logical or operator.

\textbf{Definition 7.} \textit{Address\_Check}

\[ SM\_Address[i, j] \leq T_{AD} \]

In Definition 7, the \textit{Address\_Check} clause is specified as a Boolean statement. In this case, the similarity for records \(i\) and \(j\) are tested using the \textit{SM\_Address} similarity matrix against a specified threshold value \(T_{AD}\).

\textbf{Definition 8.} \textit{Contact\_Check}

\begin{itemize}
  \item \texttt{SM\_Email[i, j] \leq T_{EM} or SM\_Mobile[i, j] \leq T_{MO} or SM\_HomePhone[i, j] \leq T_{HP} or SM\_WorkPhone[i, j] \leq T_{WP} or SM\_Fax[i, j] \leq T_{Fax}}
\end{itemize}

The \textit{Contact\_Check} checks the similarity for records \(i\) and \(j\) against a list of contact similarity metrics: \textit{SM\_Email}, \textit{SM\_Mobile}, \textit{SM\_HomePhone}, \textit{SM\_WorkPhone}, and \textit{SM\_Fax}. Each similarity matrix had its assigned threshold \(T_{EM}\) for \textit{SM\_Email}, \(T_{MO}\) for \textit{SM\_Mobile}, \(T_{HP}\) for \textit{SM\_HomePhone}, \(T_{WP}\) for \textit{SM\_WorkPhone} and \(T_{Fax}\) for \textit{SM\_Fax}.

\subsection{5.2 Family Rules}

\textbf{Definition 9.} \textit{Client-Family\_Rule}

\begin{itemize}
  \item \texttt{[LastName\_Check]}
  \item \texttt{[Contact\_Detail\_Check]}
\end{itemize}

In Definition 9, we introduce the \textit{Family\_Rule} as a rule which must have two separate clauses, each separated by a logical \texttt{and} operator. In this rule, the two clauses included are Definition 5 and Definition 8.

\subsection{5.3 Domicile Rules}

\textbf{Definition 10.} \textit{Client-Domicile\_Rule}

\begin{itemize}
  \item \texttt{[Address\_Check]}
\end{itemize}

In Definition 10, we introduce the \textit{Domicile\_Rule} as a rule which tests the domiciled clients using clause Definition 7.

\section{6 EVALUATION}

In order to provide a validation as in-depth as possible, we ran 3 different sets of experiments, with different configurations and thresholds. Experiment 1 used all of the similarity matrices presented in Table 1. Exp1.1 used a blocking method with a length of 3 for \textit{BirthDate} (DOB), \textit{FirstName} (FN), \textit{LastName} (LN); for all contact details (Contact) - \texttt{Address, Email, Mobile, HomePhone, WorkPhone} and \texttt{Fax} - the length of blocking is 6.

Experiment 2 used similarity matrices 3 to 9 (a combination of last name and all contact details) from
Table 1, using 2 different blocking configurations. 
**Exp2.1** used a blocking of length of 3 for *LastName* and length of 5 for all contact details while **Exp2.2** used a length of 6 for all contact details. Finally, experiment 3 used similarity matrices 4–9 (contact details only) with 3 different blocking configurations. In **Exp3.1**, the length is 4; in **Exp3.2**, the length is 5; and finally, in **Exp3.3**, the length of blocks is 6.

### 6.1 Results

We use 2 tables to present our results: Table 3 presents the configuration details for each of 6 experiments while Table 4 presents the total matches and accuracy for different thresholds across all 6 experiments. The accuracy is calculated depending on the labeled real-matches provided by the industry partner.

The first column in Table 3, *Exp*, is the label for the 3 sets of experiments, each with different configurations for the block length (*Block Length*) and *n/a* indicates that this attribute was not used in the segmentation experiment.

The *Dims* column lists the number of similarity dimensions used in the segmentation process. *Records* refers to the size of the recordset involved in that experiment with the total number of segments created listed in the *Segment* column. The total number of records compared for a single dimension of the similarity matrix are shown in *Comparison*. The number of records in the largest segment is shown in *Max* and finally, the *Time* presents the running time in hours consumed for each experiment while using 7 cores in parallel during pairwise comparison.

The goal of our research is to achieve the maximum number of matches while identifying any limitations caused by threshold values for each rule. Thus, our evaluation is focused on measuring matching accuracy, as validated by our industry partner. In certain cases, they require very high levels of accuracy while in other cases, they are happy with a reduced level if we can provide far higher numbers of matches. The results in Table 3 show that decreasing the length during blocking will decrease the number of segments created but an increase in segment size will see an increase in the number of comparisons required. Experiment running time is dependent on the number of comparisons in each experiment.

For all 6 experimental configurations, we ran 4 client matching experiments, 3 client-family experiments and 1 experiment for co-habitants, as shown in Table 4. Rows 2 to 5 (labelled with rules *CC0*, *CC1*, *CC2* and *CC3*) show the results of matching by the *Client-Client Rule* with threshold values from 0 to 3 for every clause. Rows labelled *CF0*, *CF1* and *CF2* show the result of the *Client-Family Rule* with threshold values of 0, 1 and 2 respectively for the two clauses in this rule. The last row *CD0* is the result for the *Client-Domicile Rule*, always with a threshold value set to 0.

The last row *Total* represents the total number of matches (*Match*) for all matching experiments (sum of *CC3*, *CF2* and *CD0*) within the listed *Exp*. The Accuracy (*Acc %*) for the total is the true accurate matches in all matching experiments divided by the *Total*.

- As expected, applying a very low threshold (distance value) will result in very high accuracy. Increasing the threshold will match more records but will, as a result, reduce the accuracy. In general terms, the number of matches increases, row by row, within each matching category.
- A higher distance threshold also captures those matches found using a lesser threshold. For example, the 35,856 matches detected in Exp2.2 using threshold *CF1* includes the 30,330 matches for *CF0* together with the additional 5,526 detected using the higher distance value of *CF1*.
- For all blocking experiments (1.1 to 3.3), where the threshold is set to 0 (*CC0*, *CF0* and *CD0*), identical records are matched and thus, the same level of accuracy is achieved. Setting the threshold to zero will override all experimental configurations; neither blocking algorithms nor matrix usage has any effect.
- If we look across the experiments, when the matching criteria is more strict (reduction in attribute comparisons), matches decrease, with the accuracy improving. For Client-Client matching with distance threshold of 2, *Exp1.1* detects 10,434 matches with an accuracy of 98.7%. However, with a similar accuracy of 99%, *Exp3.3* loses 95 records (10,339). This appears to indicate a strong case for using contact details only.
- Overall, *Exp2.2* was chosen as best because it included all the accurate matches and is efficient while constructing the similarity matrix. The number of true matches can be calculated by multiplying the number of matches (*Match*) by the accuracy percentage (*Acc %*). The total of true matches in *Exp2.2* is 35,848 (*Total × Acc %*). Across three matching rules: 10559 (*CC3 × Acc %*), *Acc %* matches identified by the *Client-Client Rule* (*C-C*); there are 23,220 (*CF2 × Acc %*) true matches identified from *Client-Family Rule* (*C-F*) and 2,069 (*CD0 × Acc %*) from *Client-Domicile Rule* (*C-D*).

6.2 Analysis

From Table 4, experiments 1, 1.1, 2.1 and 2.2 performed best in terms of detecting most matches. The total figure, calculating by adding the best performing threshold experiments (CC3, CF2 and CD0) ranges between 83,458 and 86,673 although accuracy drops when detecting high numbers of matches. Of these, Exp 2.2 is the most efficient due to the far lower number of comparisons required (see Table 3). This is to be expected as the blocking length increases and number of attributes reduced. Note that the overall accuracy is affected by the low accuracy for co-habitants (discussed later).

It is useful to note the numbers of dimensions used for matching (as opposed to segmenting) when discussing these results. In Client-Client matching, 3 clauses (9 dimensions) are used; in Client-Family matching, 2 (7 dimensions) are used and for matching co-habitants only 1 clause (1 dimension) is used. Thus, the quality of matching will inevitably decrease as we discuss the different types of matches.

Our related research highlights the many approaches to record linkage and it is no surprise that, using a combination of these techniques, the Client-Client Rule performance has the best accuracy across matches. The 0.05% (5) false matches that occurred in CC0, were as a result of the poor data quality for the Address attribute. When providing address information, only 49% of clients provided the address detailed to door number and thus, all clients on the
same street would be matched. The same quality issue for Address will result in false hits across all types of matches even where the distance threshold is set to 0.

The Client-Family Rule is generally not part of record linkage research. As expected, in sparse datasets (datasets with low numbers of client-client matches), the system detected more Client-Family matches. Interestingly, the optimum distance threshold is different. While we still have a significant change with threshold setting 2 and 3, there is enough deterioration in results between 1 and 2 to select a threshold setting of 1 (CF1). However, in Exp. 1.1, there were 30,330 matches detected with an accuracy of 72.14%. By increasing the distance threshold to 1, while this detects an extra 5,727 records, only 1,239 were accurate resulting in a drop in overall accuracy to 64.12%. For this category, it is not definitive if CF0 (all experiments produce the same number of matches so we choose 3.3 as the most efficient) or CF1 had more matches, but more checking and false positives (choose 2.2 as the most efficient combined with the higher matches).

The Client-Domicile Rule did not perform well either on accuracy nor on the number of true matches. The accuracy for co-habitants is very low even though the threshold was set to 0. The poor quality of Address is problematic for this match type, because SM_Address is the only similarity matrix used in this rule. Our fuzzy matching (threshold greater than 0) can handle abbreviations like ‘rd’ for ‘road’, ‘st’ for ‘saint’ in the Client-Client Rule and Client-Family Rule only because those rules required a higher dimensionality (used additional similarity metrics). In summary, while the number of false hits is high, it succeeded in providing a new dimension to the relationship graph for our industry partner.

7 CONCLUSIONS

Strategic business knowledge such as Customer Lifetime Values for a customer database cannot be delivered without building full customer records, which contain the entire history of transactions. In our work, we use real world customer datasets from the insurance sector with the goal of uniting client records by: connecting all records (various policy data) for the same client; connecting clients to family members (where both have policies); and connecting clients with co-habitants (where the co-habitant is also a client). As data is never clean, this is a significant task, even for relatively large datasets.

In this research, our goal was to segment the overall dataset so as to reduce matching complexity but to do so in a manner that kept ”matching” records in the same segment. Early experiments were quite clear that an aggregated similarity matrix did not provide the required matching granularity to deliver accurate results. For this reason, we create a multidimensional similarity matrix and applied a set of rules to assist the matching process. Our results show very good matching results when comparing client-to-client data; quite good results when matching clients with family members and mixed results when trying to detect cohabiting policy holders. Evaluation was provided by our industry partner who, as a result of our work, are building far larger customer graphs (customer profiles) than was previously possible. For future work, our goal is to develop an auto-validation method similar to (McCarren et al., 2017) to remove anomalies while replacing the current human checking process performed by our industry partners. This work will also incorporate precision and recall in larger datasets.
