**Keywords:** Medical Imaging, Deep Learning, Text Detection, Image de-identification, Open-Source Software.

**Abstract:** While the de-identification of DICOM tags is a standardized, well-established practice, the removal of protected health information burned into the pixels of medical images is a more complex challenge for which Deep Learning is especially well adapted. Unfortunately, there is currently a lack of accurate, effective, and freely available tools to this end. This motivates the release of a new benchmark dataset, together with free and open-source software leveraging dedicated Deep Learning algorithms, with the goal of improving patient confidentiality. The proposed methods consist of adapting scene-text detection models (SSD and TextBoxes) to the task of image de-identification. Results have shown that fine-tuning such generic text detection models on medical images significantly improves performance. The developed algorithms can be applied either from the command line or using a Web interface that is tightly integrated with a free and open-source PACS server.

## 1 INTRODUCTION

Deep Learning (DL) methods have been applied to a variety of different medical tasks, such as tumor segmentation (Bakas et al., 2018), organ segmentation (Wasserthal et al., 2023), or free-text analysis (Johnson et al., 2020). Since hospitals generally have neither the technical expertise nor the computational resources in-house, they need to be able to export their patient data to researchers for the training of DL models. More generally, collecting medical data as open-access databases has become a major challenge for the development of artificial intelligence in the healthcare sector. Collecting such data requires not only patient consent but also the use of automated tools that can prevent the revelation of patient identity.

The de-identification of electronic health records (EHR) is a well-established practice (Vithya et al., 2020). In the context of medical imaging, the official DICOM standard defines multiple so-called “Application-Level Confidentiality Profiles” that list which DICOM tags must be removed or cleared

to preserve patient confidentiality. However, imaging modalities can store protected health information (PHI) not only in the DICOM tags but also as texts that are directly burned into the raw pixels of medical images. This for instance frequently happens with radiography, mammography, and ultrasound imaging modalities. Therefore, the detection and removal of PHI that is burned into the raw pixels data of medical images is an important concern to prevent the leakage of personal information through the raw pixels of medical images. Yet, this process is rarely applied in the clinical routine, because of a lack of dedicated, easy-to-use, freely available tools.

The de-identification of burned-in PHI is intricately linked to the task of detecting texts in 2D scenes. Indeed, once a PHI text has been detected, its bounding box can easily be wiped out from the pixel data to generate a de-identified DICOM instance. In recent years, numerous open-access scene-text detection benchmarks have been released, such as the IC-DAR competition databases (Lucas et al., 2003) and the SynthText generator (Gupta et al., 2016), along with dedicated evaluation protocols, which has enabled the development of new state-of-the-art DL architectures. Nonetheless, the performance of such DL models have not been widely studied in the context of PHI detection and removal in medical images

<sup>a</sup>  <https://orcid.org/0009-0006-7135-3809>

<sup>b</sup>  <https://orcid.org/0009-0001-5335-7682>

<sup>c</sup>  <https://orcid.org/0000-0003-3275-3333>

<sup>d</sup>  <https://orcid.org/0000-0001-6685-7398>

yet: The main challenge that currently prevents the direct application of DL-based models to burned-in text detection in medical images is a lack of dedicated, annotated databases. Indeed, most existing open-access medical image databases, notably The Cancer Imaging Archive (TCIA) (Clark et al., 2013), contain only a few instances of burned-in texts, which are not specifically annotated.

According to this discussion, this paper presents a new benchmark dataset for text detection in medical images, along with effective fine-tuned versions of the “single-shot multi-box detector” (SSD) (Liu et al., 2016) and TextBoxes (Liao et al., 2017) algorithms. The developed models have been evaluated against pre-trained versions of “Efficient and Accurate Scene-Text detector” (EAST) (Zhou et al., 2017) and DPText-DETR (Ye et al., 2022) architectures, demonstrating significant improvements for burned-in text detection in medical images. This highlights the importance of fine-tuning such DL models on task-specific databases, which also justifies our development and release of open-access databases to foster further research in this domain. As a final contribution, two free and open-source tools to automatically remove burned-in texts in medical images are released, the former working from the command line, while the latter is a Web interface that is integrated with the Orthanc PACS server (Jodogne, 2018).

## 2 RELATED WORK

This section introduces different techniques used for burned-in text detection in medical images, both before and after the rise of DL for scene-text detection.

### 2.1 Image Processing for Burned-in Text Detection

One of the earliest methods applicable to PHI detection and extraction in images consisted of detecting texts using Daubechies wavelets (Wang et al., 1997). This method is based on the characteristic diagonal variations in the frequency domain observed in most Roman characters and Arabic numbers.

More recent work performs text detection using heuristic observations on the properties of medical images. A first technique proposes to separate texts from the background by analyzing the variance of pixel values in some regions of interest (Yingxuan et al., 2010). Based on similar observations, another multi-step pipeline has been proposed to isolate texts by progressively applying low- and high-threshold filters, along with morphological transformations such

as dilation (Newhauser et al., 2014). Both the latter techniques use an Optical Character Recognition (OCR) post-processing to filter out false detections (i.e., detected regions without texts). A major limitation of these approaches is that they are not easily reproducible, as neither their code nor a benchmark dataset is publicly available.

### 2.2 Deep Learning for PHI Detection

Since the rise of DL, most new PHI algorithms prioritize text recognition (OCR) over text detection. The objective is to reduce false positives while retaining valuable non-PHI data, such as positional annotations, as emphasized by the Canadian Association of Radiologists (William et al., 2021). Recent advancements differ in OCR model training, using either real-world images (Vcelak et al., 2019) or a manually annotated private database of medical images (Monteiro et al., 2017). In the latter methods, contour analysis implemented by OpenCV (Bradski, 2000) is used for the initial text detection.

This paper concentrates solely on text detection in medical images, not on recognition. A plausible reason for the prevalent focus on OCR might be the lack of a comprehensive, openly accessible benchmark dataset for burned-in text detection. Existing medical de-identification datasets, like those mentioned by Rutherford et al. (Rutherford et al., 2021), are focused on DICOM tags anonymization, while pre-existing burned-in text is ignored, which highlights a lack of resources for training PHI detection DL models.

### 2.3 Deep Learning for Generic Text Detection

Contrary to PHI detection in medical images, the general task of scene-text detection has received much attention in recent years, leading to the development of numerous model architectures, evaluation methodologies, and benchmark datasets. In turn, this large amount of annotated data has enabled the development of powerful DL-based methods for scene-text detection. These models are often separated in two main categories: region-proposal models such as SSD (Liu et al., 2016), TextBoxes (Liao et al., 2017), or DPText-DETR (Ye et al., 2022), and segmentation-based models that perform prediction at a pixel-level, such as EAST (Zhou et al., 2017). This work will focus on the four aforementioned models, as they are all available as free and open-source software, which enables an independent comparison of their applicability to text detection in medical images, with and without fine-tuning.

The two first models, SSD (initially designed for object detection) and TextBoxes (the extension of SSD to text detection), operate through a single pass of a deep Convolutional Neural Network (CNN), which balances speed and accuracy by using multiple convolutional layers to detect objects or texts at various scales. A notable aspect of these models is their use of “default boxes” of varying shapes and scales. During inference, they assess the confidence score (i.e., the likelihood of an anchor containing an object or text), and the relative offset to adjust the anchor to the specific object or text. As shown in Figure 1, a non-maximal suppression step is performed to remove overlapping boxes. Such a technique is largely used in object detection models, including EAST.

In contrast, segmentation-based models such as EAST predict the text position at a pixel level. Similarly to SSD, EAST uses CNN to detect text regions directly, although without the need for anchors. Finally, recent architectures, like DPText-DETR, tend to use Transformers-based architectures to predict text regions with dynamic points, through an encoder-decoder architecture. This work studies the impact of fine-tuning the SSD and TextBoxes models on our new benchmark dataset for text detection in medical images, and compares their performances against more advanced generic scene-text detection models (EAST and DPText-DETR) without fine-tuning.

## 2.4 Text Detection Evaluation Protocols

In addition to benchmark datasets for generic scene-text detection, dedicated methodologies to evaluate the performance of the text detection algorithms have been proposed, with variations in the computation of the precision (P), recall (R), and F-beta (F) scores. The ICDAR and DetEval evaluation protocols are nowadays widely accepted<sup>1</sup>.

### 2.4.1 ICDAR Detection Protocol

The ICDAR protocol defines the best match  $m(r, \mathbf{R})$  for a rectangle  $r$  in a set of rectangles  $\mathbf{R}$  as:

$$m(r, \mathbf{R}) = \max_{r' \in \mathbf{R}} m_p(r, r') \quad (1)$$

In this formula,  $m_p(r, r')$  represents the match between two rectangles  $r$  and  $r'$ , calculated as their area of intersection divided by the area of the minimum bounding box containing both rectangles. Based on this definition, P, R, and F scores can be computed as:

$$P = \frac{\sum_{r_e \in E} m(r_e, T)}{|E|}, \quad R = \frac{\sum_{r_t \in T} m(r_t, E)}{|T|}, \quad (2)$$

<sup>1</sup>This paper directly uses the software scripts for ICDAR and DetEval that are published on the Robust Reading Competition Website, with their default settings.

$$F = \frac{1}{\alpha/P + (1 - \alpha)/R}, \quad (3)$$

where  $T$  (resp.  $E$ ) represents the set of ground truth (resp. estimated) rectangles, while  $r_t$  (resp.  $r_e$ ) corresponds to a ground truth (resp. estimated) rectangle. In these definitions,  $\alpha$  is a weighting parameter, which is typically set to 0.5 in the official evaluation script.

### 2.4.2 DetEval Detection Protocol

The ICDAR protocol might not effectively handle the one-to-many (i.e., splitting a single prediction to match multiple targets) and many-to-one matches (i.e., merging multiple predictions to match a single target), which may lead to an underestimation of the algorithm performance. The DetEval protocol was introduced to incorporate area overlap and object-level evaluation (Wolf et al., 2006).

In the context of the DetEval protocol, the metrics of interest are  $P'$  and  $R'$  and are based on an analysis of the “overlapping matrices”, where a non-zero value at index  $(i, j)$  indicates an overlap between the detection  $D_i$  and the ground truth  $G_j$  (Liang et al., 1998):

$$P' = \frac{\sum_i \text{Match}_D(D_i, G, t_r, t_p)}{|D|}, \quad (4)$$

$$R' = \frac{\sum_j \text{Match}_G(G_j, D, t_r, t_p)}{|D|},$$

In this definition, the  $\text{Match}_D$  and  $\text{Match}_G$  are functions that consider the distinct types of matches. The parameters  $t_r$  and  $t_p$  are thresholds that define the minimal area proportion of  $G_j$  (resp.  $D_i$ ) that should overlap with ground truths (resp. predictions).

## 3 METHODS

As motivated by the discussions above, this section first introduces a new, semi-synthetic benchmark dataset for burned-in text detection in medical images. Secondly, adaptations to the generic SSD and TextBoxes architectures are proposed to improve their performances on medical images.

### 3.1 Dataset Generation

The dataset creation methodology was directly inspired by the SynthText (Gupta et al., 2016) and the DICOM dataset (Rutherford et al., 2021) generators. After selecting real medical images, random synthetic text was generated and burned into the pixel data. Figure 2 depicts some examples from our dataset.

Figure 1: The SSD architecture (Liu et al., 2016).

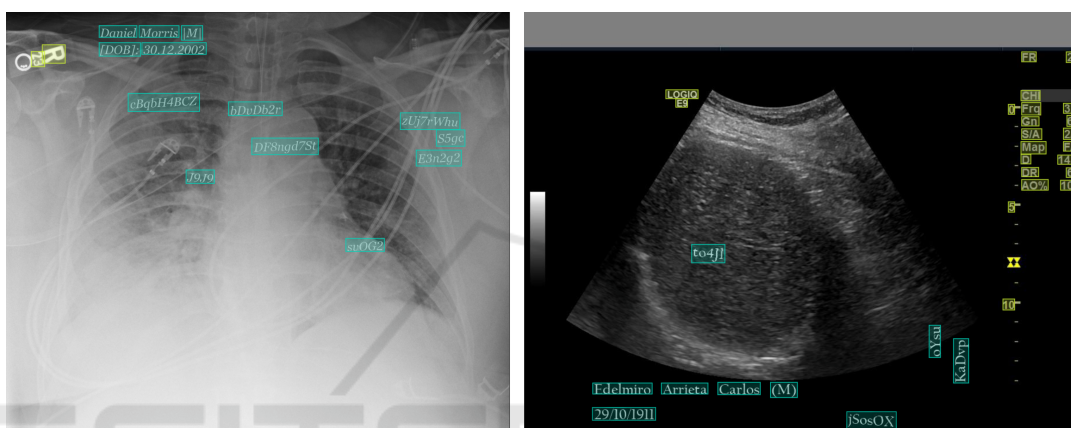

Figure 2: Examples from our dataset. Cyan annotations represent synthetic text, while yellow ones denote pre-existing text.

### 3.1.1 Original Image Collection

The first step has been to collect a large variety of real-world DICOM instances. To this end, the TCIA project has been taken as a starting point (Clark et al., 2013). A total of 1,944 images were selected from various studies corresponding to medical imaging modalities prone to having burned-in text, notably digital radiography (DX), computed radiography (CR), and medical ultrasound (US)<sup>2</sup> A conversion process was undertaken to transcode the original DICOM format into the JPEG format, making medical images easier to integrate to popular DL frameworks.

### 3.1.2 Training, Validation, and Test Subsets

Upon visual inspection of the 1,944 accumulated images, 121 images have been identified as free of burned-in texts, while 1,823 images contained

<sup>2</sup>The following TCIA datasets were used: ACRIN 6667 (Lehman et al., 2007), ACRIN 6668 (Machtay et al., 2013), B-mode-and-CEUS-Liver, COVID-19-AR (Desai et al., 2020)(Jenjaroenpun et al., 2021), COVID-19-NY-SBU, LIDC-IDRI (Armato et al., 2011), Pseudo-PHI-DICOM-Data (Rutherford et al., 2021), RIDER Pilot, TCGA-BLCA, TCGA-KIRC, and TCGA-UCEC.

burned-in text. From the latter, 276 images have been manually selected to ensure a broad diversity of backgrounds and modalities. These 397 images have been randomly divided into training, validation, and test sets with specific criteria: The test set includes 100 images with burned-in texts, the training set comprises 60% of both the remaining images with text and those without text, and the validation set consists of the remaining images.

### 3.1.3 Text Annotation

The bounding boxes of the already existing burned-in texts in the 276 images have been manually annotated using the online annotation tool `makesense.ai`. The annotated regions were then exported using the popular COCO file format (Lin et al., 2014). In this format, the boxes are stored as  $(x, y, w, h)$  tuples, where  $(x, y)$  denotes the coordinates of the upper-left pixel, and  $w$  (resp.  $h$ ) denotes the width (resp. height) of the box.

### 3.1.4 Synthetic Text Generation

To augment the amount of data and the variety of text fonts, sizes, colors, and locations, random synthetic text has been added to the images in the train-

Table 1: Statistics of the semi-synthetic dataset.

	Training	Validation	Test
# background	177	120	100
# images	17 280	11 730	100
# texts	297 281	198 300	448
# synthetic (%)	85.20	85.14	0

ing and validation sets. Synthetic PHI text has also been burned in the image, such as patient name, gender, and date of birth, using the Python Faker library. Both PHI and random texts have been placed at random positions with various fonts, sizes, colors, and orientations for diversity while ensuring that texts do not overlap, do not exceed the image, and have a minimal contrast against the background. The test set has not been modified to keep it as realistic and representative as possible. Table 1 provides statistics about the resulting semi-synthetic dataset. The resulting dataset is publicly available for download.

### 3.2 Refinements to Model Architectures

This section describes the modifications that have been applied to the SSD and TextBoxes model architectures to better fit the specific aspects of burned-in text detection in medical images compared to regular scene-text detection.

#### 3.2.1 Model Truncation

In the traditional object detection context, deeper layers of the neural network are responsible for detecting larger-scale objects or text (cf. Figure 1). However, in the context of medical images, large-scale texts never occur. Consequently, the proposed architecture only keeps the three first detection blocks and removes the last ones. This modification led to slight improvements in the performance metrics.

#### 3.2.2 Modification of TextBoxes Anchors

In both models, each prediction layer is associated with a set of *default boxes* or *anchors*, of various shapes and sizes, that are carefully designed to deal with specific tasks. TextBoxes is designed to focus on horizontal texts: It has wider default boxes along with a second row of boxes with a vertical offset that targets paragraphs. However, experiments revealed that this second row hindered text detection in medical images, in which PHI rarely takes the form of a paragraph. Removing these vertically offset boxes from TextBoxes significantly improved performance on medical images. This modification is specific to TextBoxes, as offset boxes do not exist in SSD.

Table 2: Performance metrics of the DL models. The “T” superscript denotes the truncated version of the respective models, as explained in Section 3.2.1.

Model	Validation set		Test set	
	ICDAR F1 (%)	DetEval F1 (%)	ICDAR F1 (%)	DetEval F1 (%)
SSD <sup>T</sup> 512	92.54	92.75	<b>84.70</b>	<b>85.83</b>
SSD 512	<b>92.91</b>	<b>93.09</b>	82.33	83.95
TB <sup>T</sup> 512	91.15	91.38	84.18	85.79
TB 512	91.11	91.37	82.34	83.60
EAST	9.25	8.26	64.77	65.95
DPTText-DETR	47.62	47.79	78.19	79.25

## 4 RESULTS

This section illustrates the benefits of the developed DL models, by analyzing their performance on the validation and test sets of the newly developed benchmark database. A comparison against the regular scene-text detection models (EAST and DPTText-DETR) is then proposed to highlight the benefits of fine-tuning the models on medical images. As a last contribution, free and open-source tools implementing the models are discussed and compared to existing open and proprietary tools.

### 4.1 General Outcomes

The results shown in Table 2 illustrate the benefits of adapting and fine-tuning the models on medical images. The original TextBoxes algorithm is not represented as its performance did not improve during the fine-tuning, leading to an F-score lower than 1%. Models have been fine-tuned for 45 epochs, with the Adam optimizer (Diederik et al., 2017) with a learning rate of 0.001. Figure 3 shows predictions obtained with the truncated version of SSD on real-world examples (i.e., without synthetic text) from our test set.

It is important to notice that EAST and DPTText-DETR have been taken *as is* from free and open-source projects, and were only trained on manually annotated detection datasets<sup>3</sup>. This is the reason why these models perform worse than the SSD and TextBoxes models after their fine-tuning on medical images. Furthermore, the fact that they were trained on manually annotated datasets, like ICDAR2019, can explain the inferior performance on the semi-synthetic validation set, as compared to our manually annotated test set. Indeed, based on a complementary

<sup>3</sup>The EAST model is available at <https://github.com/SakuraRiven/EAST>, and DPTText-DETR at <https://github.com/ymy-k/DPTText-DETR>

Figure 3:  $SSD^T$  predictions on 2 samples from our test set.

evaluation, the Intersection-over-Union between synthetic and predicted boxes rarely exceeds 60%, and is thus evaluated as non-matching, lowering actual detection performances. Nonetheless, the results of the test set clearly illustrate the specificity of medical images as compared to world scene images, which calls for the development of additional benchmark datasets dedicated to the detection of texts burned in medical images that could be used to fine-tune DL models.

## 4.2 Evaluation

The results shown in Table 2 have been obtained with a confidence threshold of 0.2 for all models except for SSD, for which the confidence threshold was set to 0.35. The selection of an appropriate confidence threshold is critical depending on the application, as it defines the balance between precision and recall: A higher threshold will filter out predictions with low scores, which increases the model precision, at the cost of a lower recall. Considering the sensitive nature of patient data, the focus should be on maximizing the recall, ensuring that most of the PHI text is detected. This therefore reduces the risk of leaking patient information during the de-identification process, at the cost of increasing false positives.

Table 3 depicts the impact of this threshold on the DetEval performance metrics for our best model, which justifies the choice of the 0.2 threshold as a good balance between precision and recall. Figure 4 compares the precision and the recall for the tested models and for the various thresholds of the best model, respectively. Since all conditions do not follow a normal distribution (all conditions did not pass a Kolmogorov–Smirnov test with  $p \leq 0.0001$ ), a Friedman non-parametric one-way analysis of variance for matched images with Dunn’s correction for multiple comparisons for both precision and recall revealed a

Table 3: DetEval metrics at varying confidence thresholds for the SSD truncate model. A comparable trend is observed under the ICDAR protocol metrics.

Confidence threshold (%)	Precision (%)	Recall (%)	F1 (%)
10	71.98	85.27	78.07
20	88.98	82.90	<b>85.83</b>
30	90.44	81.56	85.77
40	91.18	78.93	84.61
50	91.90	77.86	84.30

significant difference between our fine-tuned models and generic pre-trained models, but not among thresholds of the best model. For both precision ( $F = 31.73$ ) and recall ( $F = 217.8$ ), we obtained  $p < 0.0001$ \*\*\*\* for  $n = 100$  images,  $n_T = 6$ . The level of significance between conditions is represented as follows:  $p < 0.05^*$ ,  $p < 0.01^{**}$ ,  $p < 0.001^{***}$ , and  $p < 0.0001$ \*\*\*\*.

## 4.3 Software

One of the main concerns of this work is to make patient confidentiality more accurate and accessible, with an open-science perspective. To this end, in addition to the benchmark dataset described in Section 3.1.4, the weights of the DL models are available as open data alongside the new benchmark dataset. Furthermore, to make the models easily applicable on real-world medical images, two new free and open-source tools are released<sup>4</sup>.

**Existing Tools.** Some de-identification tools are already available, such as Microsoft Presidio Image Redactor and Google Healthcare API. Presidio, still in beta as of writing, is an open-source, configurable

<sup>4</sup>Their code is available at: <https://forge.uclouvain.be/QuentinLanglois/medical-image-de-identification-tools>

Figure 4: P and R rates of the models (1-2) and of the best model thresholds (3-4). Error bars show a confidence interval of 95%.

tool that detects and redacts PHI in medical images using the Tesseract OCR framework. Its main limitation is the efficiency on medical images, hindered by a lack of dedicated fine-tuning. Google Healthcare API, in contrast, is a proprietary solution that offers extensive documentation and allows for extensive customization in the de-identification process. However, it incurs significant operational costs and its closed-source nature restricts its reproducibility.

**Proposed Tools.** To address these limitations, we introduce a new free and open-source software for burned-in text removal. Our tools do not rely on OCR for non-PHI filtering and remove all detected texts, which is generally preferred to avoid sensitive information leaks. Future enhancements may integrate OCR to overcome this limitation. The command-line tool offers an efficient solution for the batch de-identification of folders containing images in various file formats (JPEG, PNG, DICOM). The browser-based tool leverages Orthanc, a free, lightweight, standalone DICOM server with a RESTful API (Jodogne et al., 2013). Our MedTextCleaner (MTC) is an interactive Web application, developed as an Orthanc plugin. It uses Python and Vue.js framework for automated text detection, allowing users to validate and manually edit as needed. A detailed demonstration video is available.

## 5 CONCLUSION

The contributions of this paper are threefold. Firstly, a new semi-synthetic dataset dedicated to the detection and removal of texts burned in medical images is published in open access. This new dataset will hopefully provide a benchmark to foster further research on DL applied to the task of image de-identification. Secondly, it has been shown that generic DL models for scene text detection can be fine-tuned on medical

images, leading to vastly improved performance. This approach contrasts with recent work, which tends to focus on OCR techniques instead of text detection methods. Finally, pre-trained models are released as open data, together with free and open-source software implementing a platform for text detection and removal in medical images. The latter contribution subscribes to the open-science paradigm by promoting transparency, reproducibility, and knowledge sharing for the de-identification of medical images.

This work is specifically focused on the improvement of the text detection techniques, without any filtering of the detected texts using OCR. Nevertheless, such filtering may be useful to keep relevant information, such as location tags or medical results, which may be relevant for some applications. Consequently, future work will explore the combination of the developed DL models with an OCR engine. The new benchmark database will also be used to assess the performance of more medical image de-identification algorithms, whether based on Deep Learning or on more traditional computer vision approaches.

## ACKNOWLEDGMENTS

The results published are in part based on data generated by the TCGA Research Network. The authors acknowledge the National Cancer Institute and the Foundation for the National Institutes of Health, and their critical role in the creation of the free publicly available LIDC/IDRI Database used in this study. Computational resources have been provided by the *Consortium des Équipements de Calcul Intensif* (CÉCI), funded by the Fonds de la Recherche Scientifique de Belgique (F.R.S.-FNRS) under Grant No. 2.5020.11 and by the Walloon Region. Quentin Langlois is funded by the Walloon Region through a F.R.S.-FNRS FRIA (Fund for Research training in Industry and Agriculture) grant.
